About the same time I had for schoolmaster in Edinburgh (and long after for a close friend) Dr. John Sturgeon Mackay, as deeply versed in Greek mathematics as Allman himself. In Edinburgh he was scarcely known save to his schoolboys, and lived a life as neglected as that still greater Hellenist Veitch (of the "Greek Verbs") had done; but he spent his vacations reading Greek MSS. in the great libraries, and in Paris he was intimate with Paul Tannery and the scholars of the day. Mackay's life-task was to edit Pappus, the one great Alexandrine omitted by the Oxford editors of the eighteenth century. After twenty years' work the thing was done, and lay in his desk with every diagram exquisitely drawn and every page and footnote written and rewritten. He went one day into Williams and Norgate's bookshop, then in Edinburgh, and the manager said: "I have something that will interest you to-day, Dr. Mackay"; and he handed him the first volume, fresh from Leipzig, of Hultsch's edition of Pappus. The two men must (as Mackay told me afterwards) have been following one another unawares from library to library, collating the same MSS., noting the same minute textual details, and Mackay's intimacy with the French had helped doubtless, in those long-ago post-war years, to keep him unacquainted with the German and his work. Anyway, there was an end of the matter. Some might have hurried into print, trusting to little points of their own, claiming something of the reward—but not Mackay. The work was done and well done. Pappus was edited. It was a scholar's tragedy—and nothing more!

Sir Thomas Heath has produced one important work after another, while living all the while a life of strenuous official toil and responsibility. His Diophantus, his Apollonius, and (greatest perhaps of all) his Euclid are part of the solid foundation of this "History of Greek Mathematics." He has had more to build on by a long way than Allman and Gow had fifty years ago; new texts have been edited, and men like Heiberg, Tannery, Zeuthen, Aldo Mieli, and (last but not least) Gino Loria have dealt with the matter in part and

whole; but the essential difficulty remains of piecing together the broken stones.

In our first glimpse of ancient mathematics two great figures, Pythagoras and Plato, stand out above all the rest: not as the greatest mathematicians, but as the greatest landmarks in history and tradition, much like Descartes and Leibniz in another age. From Plato on, the story runs fairly smooth; we leave tradition behind and enter upon history; mathematics becomes a science of its own and slowly disentangles itself from philosophy; the "polymath" is giving place to the specialist. With Euclid we enter on the "Golden Age" of geometry cradled in Plato's Academy, and though some of the minor men (like Nicomedes and Diocles) remain shadowy figures, we have a solid inheritance in Euclid and Apollonius and in Archimedes—"ordine quidem tertius" (as Torelli said), "dignitate facile princeps." On the physical side the astronomy of Eudoxus, the Optics of Euclid, the astronomy again of Aristarchus—the "Copernicus of antiquity"—may be taken as "nails in a sure place"; and when we come to the "Silver Age" of Diophantus, Pappus, Ptolemy and Theon, we have a wealth of historical material.

But up to Plato's time it is a very different story, for the simple reason that very few of the earlier philosophers and mathematicians (say down to Archytas) ever *wrote* at all. Their teaching was private or even secret, and only oral tradition carried it on. Two things men will continue to discuss but never know for sure—the debt the first Greek mathematicians owed to Egypt and the East, and the real, actual attainments in mathematics of men like Thales, Pythagoras, Archytas, Democritus and Plato. Pythagoras is the strangest case of all, for no wise man's name since Solomon's has so fascinated the world. Tradition, and tradition alone, tells us that he invented the forty-seventh proposition, and tells it no more confidently than the Dancing Dervishes of Constantinople tell you they are the descendants of his holy Brotherhood!

Where there is nothing but tradition to go upon, the historian is lost. The imaginative man begins putting two and two together, arguing what *must* have been known in order to know this or that, and what *must* have followed as soon as this or that was understood; and so the story grows. The construction of the Pentagon "must" have implied a knowledge of the Golden Section, and this and the "Theorem" itself must have involved the concept of the Irrational; the triangle of the Pentalpha and its gnomons must have led on to the logarithmic spiral—even to the Limaçon of Pascal! In some such way Naber, for instance, discourses on what Pythagoras "must" have known and what he may have known; it is pleasant, even suggestive, reading, but it is a long, long way from history. At the other end stand the sceptical critics, to be taken more seriously—like Eva Sachs, whose book, by the way, on "Die fünf platonischen Körper," Heath does not seem to quote. She, for example, holds that up to Philolaus we know nothing at all; that he and later Pythagoreans were chiefly bent on ascribing each new thing to the old master of their school; that there is no proof that Pythagoras knew anything of irrationals, little that he was acquainted with the regular solids, and none at all that he associated them, *more Platonico*, with a theory of the Elements. Between such opinions Sir Thomas Heath steers a careful middle course, and what he has to tell he attributes to "the Pythagoreans" rather than to Pythagoras.

Again, as to alien sources behind early Greek mathematics, one school will tell you that Greece had nothing or next to nothing to gain from the land-surveyors or "rope-stretchers" of Egypt, nor from Mesopotamian astronomers and calendar-makers. Others eagerly pick up little stray hints of a community or descent of ancient learning. They remind us that it was in Ionia that Greek philosophy arose and the special sciences, even medicine, began—in a "mélange de races d'émigrés, d'origine diverse," as Heiberg called the Ionians the other day; that Ionia was in close and constant touch with Lydia; and that Ionian science appeared after a clash of empires and fall of cities, as a later Renaissance followed the fall of Constantinople. Or they catch hold of straws which point, or seem to point, to Far Eastern intercourse, such (for instance) as that mode of reckoning by myriads and myriads of myriads which the Japanese are said to have used about the time (say) of Thales, which exists in China to this day, and seems identical with Archimedes' famous numeration of the *Arenarius*—where he began by supposing a myriad grains of sand in the space of a poppy-seed (or rather surely a poppy-*head*), and went on to myriad-myriads of units, and of orders, and of periods. Heath discusses the broad question briefly and fairly, and is content in the end to agree (as we all must) with Plato, that whatsoever the Greeks had borrowed, were it much or little, they it was who improved on it and carried it towards perfection. The Greeks at least knew well what not to borrow, and striking above all else is their choice of themes. It is they who best exemplify what Sir John Herschel laid down (perhaps rightly) as a general proposition—that men delight to escape from the trammels of earth: that not practical problems but "the abstractions of geometry, the properties of numbers, the movements of the celestial spheres, whatsoever is abstruse, remote and extramundane, become the first objects of infant

science." The useful applications, mechanical inventions, follow later on; and David Hume put it neatly when he remarked that "we cannot reasonably expect a piece of woollen cloth to be brought to perfection in a nation that is ignorant of astronomy."

Two things attract the general student, I think, more than any others connected with Greek mathematics—the Pythagorean arithmetic and the matter of the Platonic bodies. The former begins with the notion, characteristically Greek rather than peculiarly Pythagorean or Platonic, of arithmetic as something apart from mere calculation or the doing of sums—as, in short, a "theory of numbers"; and not the least curious thing about it is that that arithmetic was studied (or so it is said) for generations before the Greeks had signs, even alphabetic ones, for the numerals. We may go to Sir Thomas Heath for a clear and full account of all the curious sorts of numbers, figurate and other, odd and even, square, triangular, and pyramidal, friendly numbers, perfect numbers, and so forth, which fertile imagination along with true mathematical insight was able to discover. It is not without a deep meaning, I believe, that we find on the very threshold of Mathematics this instinct for the symmetry of numbers, this sense of the intrinsic beauty, the comparative perfection, of one number or another. It is the way the calculating boy begins; we had it exemplified in the highest degree, only the other day, in Ramanujan's extraordinary but too short-lived talent. The theme, in Greek hands, leads on and on by many roads. By way of the "means," it is at the root of the theory of music itself, of the "acousmatic" side of the Pythagorean philosophy; by the theory of "gnomons" it is close-linked with the "theorem" of Pythagoras; it carries us, though more in contrast than identity, to the Euclidean treatment of arithmetic; and at last it brings us straight to the Neo-pythagoreans, to the "Theologumena," and to later writers down even to Kircher, who dealt more and more extravagantly (much after the fashion of the Cabbala) "de abditis numerorum mysteriis"—with the physical, the "ethical" and the "theological" properties of numbers.

The other matter, that of the Platonic bodies, is a long story. We know that Plato did not discover them but we may still be curious to know whether Pythagoras did; and here we must distinguish the mathematical side of the question from the physico-philosophical one—from the deeper meaning which Plato and others found in these five symmetries. It has been amply shown, I think, that their association with the elements was not due to Pythagoras, and it is not likely that Pythagoras knew very much even about their construction and properties. To suppose him to have understood these is to credit him with too much; the main teaching of Euclid would have been already his: "Le cadre était déjà celui," as Tannery says, "que remplissait les Eléments [d'Euclide]." But who were the great mathematicians who investigated them? Theætetus was probably the outstanding man—he who "*described*," that is *constructed*, the five solids, according to Suidas—though Heath hesitates (curiously) over the meaning of ἔγραψε. Heath quotes also the Euclid-scholion that Theaetetus added the octahedron and icosahedron to the other three, but I do not think he mentions that this has (or so it might seem) a textual flaw; for surely the octahedron was as old as the Pyramids, while the *dodecahedron* would be one of the last, probably the last of all, to be constructed and explained. Plato, then, may have taken his mathematics in this matter from Theaetetus, partly (some would say) from Democritus, and something more straight from Leucippus. So with their help was built up Plato's theory, fanciful no doubt but very beautiful, of these five figures, all inscribable in spheres, not really solids but hollow shells with filmy surfaces, made out of tiny triangles—as the gold-beater begins with little three-sided patins of gold—the figures being, as it were, molecules with the facets for atoms, and the whole forming a sort of foamy, cellular structure, like a froth of soap-bubbles, out of which to build the material of an harmonious world. Indeed, one wonders whether Plato had not in his mind's eye the homely but exquisite configuration of a froth of soap-suds!

The theme is kindred to our last. For just as an arithmetic grew up regardless of practical reckoning and dealing only with the symmetrical properties of numbers, so did a geometry arise which thought nothing of practical mensuration, only of the abstract properties, the essential symmetries, of planes and solids. This geometry, which studied the triangle, the square, the pentagon, etc., then the "Platonic" and "Archimedean" bodies, the regular and semi-regular solids, the perfect, the less perfect and the imperfect geometrical forms, was own sister to that arithmetic which investigated the triangles, squares, polygons, pyramids and cubes, the "perfections and imperfections," which lie hidden among the mysterious properties of numbers. And all the while these theoretical studies of *configuration* were being applied along somewhat narrow but very important lines to music, to optics and to astronomy, as we should say to problems of sound, light and periodic motion—in short, to the three great recognised groups of harmonious natural phenomena. This, then, in a word, was the concept of Greek mathematics as it occupied the wit of man, the intellect of philosophers, for just a thousand years.

The Archimedean bodies, by the way, Heath deals with pretty fully, but he might perhaps have told us that one of these (Kepler's "truncated octahedron"), said to have been known to Plato, is no other than that tetrakaidekahedron which Lord Kelvin showed to be (with a slight modification) the typical "cell" of a homogeneous froth. He might even perhaps have told us a little of how Kepler (true disciple of Pythagoras and of Plato) used both Platonic and Archimedean bodies in that treasure-house of elegant geometry, the "Harmonice Mundi"; and how he showed that not only the five Platonic bodies (as Euclid knew) but also Archimedes' thirteen were all there are, the complete series of their respective families.

There is a vast deal of information in Heath's book, clearly set forth and orderly arranged; we have nothing to compare with it in English, and Gino Loria's "Scienze esatte" is its only serious rival abroad. I am inclined to think that Loria paints history with a broader brush, while Heath excels in his account of individual mathematicians; but I cannot help thinking that Heath, who has attained such complete and acknowledged success in his editions of Euclid and the rest, must have found that in this history he had struck a harder task than any he had tried before. We may know more of the history of mathematics than of any other science, but the lacunæ are immense, and tradition is poor material for the historian. Moreover the historical aspect is somewhat uncongenial to the mathematician, if only because (as Eva Sachs says) history deals with *das Werden*, and mathematics with *das Sein*!

When Sir Thomas Heath deals with Euclid, Apollonius, Archimedes, Diophantus, Hero or Pappus, he gives us in a few pages all we could expect by way of epitome of the trend, the method and the results of their labours. But his book pursues its steady, instructive course with little digression, allusion or anecdote, and with curiously little bibliographical information such as he puts abundantly into his other books. Surely one of the objects of a text-book is to guide the student to what it does not and cannot contain! Some of us, I think, would have liked a little more digression or even gossip. When Sir Thomas has told us that the Pentalpha was the Pythagorean symbol of Health he is well-nigh done; but Chasles gives us a dozen pages of learned gossip upon it, traces it through Boetius and Thomas Bradwardine and the Margarita Philosophica and Father Kircher to Kepler himself, and ends with Poinssot's "Mémoire sur les Polygones"! The Shoemaker's Knife is a beautiful and simple construction in easy geometry, of great antiquity—an ancient proposition, Pappus calls it—and Heath tells us doubtless all that is essential for us to know; but a short footnote might have told us how Jacob Steiner investigated and elaborated it, or how J. S. Mackay epitomised its many properties, or how Sir Thomas Muir added a pretty corollary.

Again (as a random instance) Heath discusses at length the simple but important rule of Thymaridas (simplicity itself in our notation) for solving certain simultaneous equations, where the sum of $x_1+x_2+\ \ldots\ x_n$ is known, and also the successive sums of x_1+x_2, x_1+x_3, etc.; but of Thymaridas he only tells us that he was "an ancient Pythagorean, probably not later than Plato's time." If we be limited to a phrase I do not know that we could say a safer thing; but why should we not have some little sign-post, even a footnote, to Tannery's discussion (in "L'Arithmétique pythagorienne") on who Thymaridas was and when he lived, or to the many discussions by Cantor, Martin, Nesselmann, and even Fabricius; for "il y a un assez grand intérêt historique à déterminer l'âge où vivait Thymaridas." Heath tells us that this rule of his was called by the special name of ἐπάνθημα, and he translates it "the 'flower' or 'bloom' of Thymaridas." He qualifies this by a parenthetic remark that the name was not, after all, confined to this particular proposition, but what it really means he does not explain; Tannery, I think, has shown fairly clearly that it was a name ("pour ainsi dire") "pour les matières non exigées du programme de l'arithmétique pour les étudiants en philosophie."

It was again Thymaridas who defined (as Heath tells us) "a unit as 'limiting quantity,'" περαίνουσα ποσότης. It was a very important definition, but was it not a definition of "unity" rather than of "a unit," and is a limiting *quantity* a fair and full translation of ποσότης? Turn towards the other end of the volume, to ground that is peculiarly Heath's own, and see Euclid's famous definition (V. 3) of *ratio*, which Heath renders "a sort of relation in respect of *size* (πηλικότης) between two magnitudes of the same kind." I cannot help thinking that, between the two, we lose the fine and even crucial distinction between ποσότης and πηλικότης. The one mathematician was talking of a relation between numbers, the other of a ratio between any two magnitudes; I think they both picked their words accordingly, and I should like at least to give them the benefit of the doubt. Of Euclid's definition Heath tells us that "it was probably inserted for completeness' sake, and in order merely to aid the conception of a ratio." All the same, I should rather like to hear what Barrow had to say of its metaphysical character; or what an older school meant when they translated

πηλικότης by *quantuplicity*; or even to be referred to that very curious imaginary discussion of this very point, by Euclid, Eutocius, Theon and the rest, in the pages of Meibom's "De Proportionibus." The simple fact is that Sir Thomas Heath has given us so much, and it is all so good, that he makes us ask for more.

D'ARCY W. THOMPSON.

Entomology and Malaria.

The Prevention of Malaria in the Federated Malay States: A Record of Twenty Years' Progress. By Dr. Malcolm Watson, with contributions by P. S. Hunter and A. R. Wellington. Second edition, revised and enlarged. Pp. xxviii + 381. (London: John Murray, 1921.) 36*s*. net.

DR. WATSON'S book shows clearly the wide range of scientific knowledge which is required by those who work in the tropics either as physicians or as sanitarians. It is unnecessary nowadays to insist upon the importance of the control of malaria in the development of those vast areas from which is derived so much of the food supplies and raw materials of manufacture of all civilised countries, but only those who have had practical experience of the methods used to deal with the disease can appreciate how many and how varied these must be.

Until about the middle of the nineteenth century medical men were almost always naturalists as well, and it is regrettable that the old traditional association of medicine and natural science has been so largely broken off. In modern times the older teaching of natural history has been replaced by an inadequate course of so-called biology which may, indeed, enable the student to recognise the appendages of the cockroach, or a section of the rhizome of a fern, but scarcely qualifies him to name correctly the commonest insect or plant when he sees it in the field. The need for a more practical knowledge of the forms and bionomics of animals, and especially of insects, is brought home to one again and again during the perusal of Dr. Watson's very interesting and readable book.

It was indeed no light task which confronted the author when in 1901 he began his service in the Malay States. The new knowledge of the mode of transmission of malaria by certain mosquitoes had to find a practical application in a country where physical conditions are very diversified and little or nothing was known about the insect carriers. Large commercial interests, too, were involved, and no doubt there were many interested persons ready to criticise adversely any failure, and reluctant to spend money on what they regarded as the doctor's theories. Here were the most favourable conditions imaginable for mosquitoes—an equable, warm, and moist climate; a large rainfall almost equally distributed throughout the year; abundance of pools, swamps, and hill-streams. As to the prevalence of mosquitoes, Dr. Watson relates that, in a small patch of jungle in the town of Klang, *Anopheles umbrosus*, a natural carrier of malaria, was present in such large numbers that three persons caught about two hundred in a quarter of an hour "and simply could not stand the biting any longer." At the same time, three other species of mosquitoes were present "in considerably greater numbers than the anopheline, so it can be imagined a quarter of an hour in that jungle was unpleasant."

FIG. 1.—Kapar Drainage Scheme. One of the main drains, with rubber-trees on both sides. From "The Prevention of Malaria in the Federated Malay States."

The book abounds with interesting details concerning the natural history of various mosquitoes, and shows how necessary such knowledge is before any attempt can be made to mitigate the malarial scourge. The case of *Anopheles Ludlowi* is a good vindication—if any were needed—of the practical importance of the taxonomic work of the systematic entomologist. There are three species, *A. Ludlowi, A. Rossii,* and *A. indefinitus,* so similar to one another that the experience of an expert is required to distinguish between them. Yet of these three only one, *A. Ludlowi,* is known to be a natural carrier of malaria. Moreover, it differs entirely from the others in its habits, breeding mainly along the coast and often in brackish water. In connection with this mosquito Dr. Watson gives a good account of the mangrove-swamps, and explains how engineering works on the coast may cause an increase of malaria by interference with the tidal flushing of the swamps.

As the prevalent mosquitoes vary in the plains and in the hills, so the methods of dealing with malaria differ in each locality. As the jungle is cleared and drained in the plains malaria disappears; whilst in the hills drainage and the opening up of the jungle alone fail to influence the prevalence of the disease. The explanation of this is that in the plains the mosquito which carries malaria is *Anopheles umbrosus,* which breeds in pools in the jungle; in the hills the mosquito chiefly concerned is *A. maculatus,* the breeding-place of which is the running water of springs and hill-streams. A method which may be quite successful in diminishing the numbers of one species may yet fail to lessen the incidence of malaria, since it may lead to conditions suitable for the breeding of another species. How all these different problems were dealt with satisfactorily will be found in the volume under review.

The book appeals to other than medical men. Many interesting sidelights are thrown on the inhabitants, on life in the Malay States, and on the development of rubber planting; a good account also is given of the physical features of the country, with its mangrove-swamps, "flat land," coastal and inland hills.

The book is written in an attractive style, and such a large amount of knowledge is so pleasantly and modestly displayed that it will certainly add much to the high reputation of the authors; and, since the methods for the prevention of malaria, which were used so successfully in the Malay States, are of general application, this lucid account will be of the utmost value to all medical men practising in tropical and subtropical regions. The book is well printed and illustrated by a large number of excellent photographs, two of which are here reproduced.

H. J. WALTON.

Berber Surgery and Sport in the Aurès Mountains.

(1) *Among the Hill Folk of Algeria: Journeys among the Shawia of the Aurès Mountains.* By M. W. Hilton-Simpson. Pp. 248. (London: T. Fisher Unwin, Ltd., 1921.) 21*s.* net.

(2) *Shooting Trips in Europe and Algeria: Being a Record of Sport in the Alps, Pyrenees, Norway, Sweden, Corsica, and Algeria.* By H. P. Highton. Pp. 237. (London: H. F. and G. Witherby, 1921.) 16*s.*

(1) THE gregarious nature of the British tourist is illustrated by Captain Hilton-Simpson's claim that during his excursions among the Algerian hills near Biskra, which he describes as one of the most popular tourist resorts of the whole world, his wife was the first European woman to be seen by many of the people of the adjacent hills. His journeys in the mountains of Aurès, the Mons Aurasius of the Romans, were conducted mainly to study the native surgery and make a collection of the instruments used for the Pitt-Rivers Museum, Oxford. The most valuable chapter in his book is the account of Berber surgery, which is not easily studied, as the French apply to the Northern Sahara the law that a fatal operation conducted by a man who is not medically qualified is manslaughter. Captain Hilton-Simpson, by gifts of drugs and surgical instruments, was able to gain the confidence of some of the native practitioners. He secured admission to some operations, and has collected much interesting information as to the methods of treatment. The most remarkable success is in trepanning.

The author has made seventeen visits to Algeria, so he knows the country well, and his book is a valuable record of contemporary native life in the remoter villages of the Southern Atlas. He refers to indications of a greater rainfall at the time of the Roman occupation, though the general evidence given in the book indicates that the climate in Roman times was much the same as it is to-day.

(2) The same district has been described from a very different point of view by Mr. H. P. Highton, a science master at Rugby. He, also, discarding the ways of the ordinary tourist, has devoted many of the generous holidays allowed at the public schools to shooting trips, in one of which he visited the mountains of Southern Algeria in quest of the Barbary sheep and the Dorcas gazelle. Other journeys were in chase of chamois in the Alps and the Pyrenees, of elk and reindeer in Norway and Sweden, and of moufflon in Corsica. Chamois-hunting he calls the prince of sport. His narratives are brightly written. He concludes with a defence of shooting based on the nature-red-in-tooth-and-claw principle, and the claim that, though animals suffer greatly from mental anguish when chased, as presumably in fox-hunting, they feel little physical pain. This line of argument is almost the opposite to that adopted by Roosevelt, based on the quickness with which wild animals forget sudden alarm.

The War and the Royal Engineers.

The Work of the Royal Engineers in the European War, 1914–19.

(1) *Water Supply.* Part I.: *General Development of Organization, Plant, and Works.* Pp. 54 + 32 pls. + 2 maps. Part II.: *Operations.* Pp. 55-92 + 9 pls. + 8 maps.

(2) *Bridging.* Pp. 87 + 33 pls. + 3 maps.

(3) *Supply of Engineer Stores and Equipment.* Pp. 109.

(4) *The Signal Service in the European War of 1914 to 1918. (France.)* By R. E. Priestley. Pp. xvi + 359 + 20 pls.

(Chatham: Secretary, R.E. Institute; W. and J. Mackay and Co., Ltd., 1921.)

(1) IN the last year of the war operations involving "concentrations of unexampled density could be successfully undertaken at short notice in any areas, and at the points most desirable for strategical or tactical reasons, without reference to the presence of water in or near the surface." The ways and means by which this result was achieved are well set forth in the work under review. Amongst them may be mentioned the erection of semi-permanent and extensive supply systems with head works and pipe-lines, such as those at Roosbrugghe, the free use of mechanical transport, and the extensive use of boring plant. Drills were used on a small scale in the chalk area in 1915, the air-lift pump soon giving a great impetus to boring operations. Portable air-compressor plants mounted on lorries visited a borehole and worked so long as was necessary to fill the local storage plants.

Scarcely less important than the supply of water was the purification of it, and full details of the methods used are given. Large purification plants did excellent work of a pioneer nature in supplying potable water from canals—in some cases through pipe-lines several miles in length.

(2) The need for heavy bridges was first experienced on the Aisne. From that time the history of bridging during the war was determined largely by the increasingly important rôle played by the heavy artillery and tanks, the maximum axle load to be carried rising from thirteen to thirty tons. With the aid of drawings and some excellent photographs, the various standard

types of bridges evolved in the campaign are passed under review. One of the most remarkable types, from the point of view of lightness and ease of erection, was the Inglis bridge of identical bays of weldless steel tubes.

The chapter on temporary bridges is a really stirring account of typical bridging operations during the final advance of August to November, 1918. A succession of waterways had to be forced before each serious engagement. In one case a field company erected a trestle bridge of 80-ft. span within 500 yds. of the enemy line, completing it four hours before the attack was launched. No fewer than 539 heavy bridges were erected between August and November, 1918.

(3) The supply of stores necessarily developed not only in quantity, but also in variety, for "it came about that the R.E. were early regarded as the universal providers of everything that was not authorised equipment." By March 1919, more than 1,800,000 tons of R.E. stores of the most diverse nature had been sent over to the Western front. Road metal, camouflage, electric-light installations, and propaganda balloons, all figured in the lists. Constantly increasing experimental work on new devices was also carried out, and the statement of the results achieved is of considerable interest.

(4) This study of the nervous system of the Army in the recent war is the story of a service constantly "struggling with ever fresh developments and responsibilities: sometimes failing, more often succeeding, and always improving and learning." The need for continual adjustment of ideas and nimbleness of thought on the part of those directing the policy of signals has not ended with the war. Just as "the discovery of the magneto telephone by the General Staff was probably responsible for a revolution in staff methods as great as any that has ever occurred in the history of war," so may the developments of wireless telegraphy and telephony bring many new problems for the signal officer of the future. While recognising fully the strangle-hold that code and cipher exercised on the use of wireless during the greater part of the war, Major Priestley points out how, as shelling and bombing became more intense, wireless forced its way more and more into use and recognition. It is clearly his view that the signals of the future will be mainly wireless supported by line telegraphy and visual work.

Few remarks throw more light on the extent to which signals grew in complexity during the war and technical qualifications came to be required by front-line troops than the statement that at the end of the war, the battalion and battery signaller was expected to have more qualifications than those possessed by the line telegraphists of the Royal Engineers at the commencement of the war.

For its system of hastily improvising a large army this country paid the penalty that must needs accompany such a process. Had we been better organised to make full use of man-power and brain-power on a national emergency, Moseley could scarcely have been allowed to go to his gallant death at Gallipoli. He could have been so much more profitably employed in his corps either in developing wireless or in examining and combating the overhearing of telephone signals. Our slowness in the recognition of enemy overhearing, with all the unnecessary loss of life that it involved, is a natural sequel to our general unpreparedness for the great emergency of 1914.

Granted that we were not always first in the field in the early days of the war, we can, however, recognise fairly that lost time was well made up before the end. The close of the war found the Signal Service "efficient in its day and generation, as the *personnel* of the highly trained units of the original Expeditionary Force had been in theirs."

Our Bookshelf.

Nut Growing. By R. T. Morris. Pp. x+236. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1921.) 13*s*. net.

There is little of the dry manual about this useful volume. The author has a "message" to give to a world seeking new foodstuffs, and though he occupies forty pages in introducing the subject, his preliminary remarks are to the point and well worth reading by those interested. Briefly, the book is a practical guide to the commercial cultivation of trees bearing edible nuts, and is addressed to growers in America, where in recent years much attention has been given to this industry. The nuts dealt with include hickories, walnuts, hazels, chestnuts, pine nuts, and almonds. Reference is made to the devastation caused in the forests of American chestnut (*Castanea dentata*) by the fungus *Endothia parasitica*, which threatens to destroy the species unless resistant stocks can be discovered and successfully propagated. The author claims to have produced hybrids between this tree and the chinkapin (*Castanea pumila*) which are highly resistant to the fungus, and bear nuts of good size and quality. An important section on propagation deals with the practical aspects of nut cultivation, and has been written mainly with the object of describing a special system of grafting, which is clearly illustrated in a series of excellent plates.

A Handbook on Cotton and Tobacco Cultivation in Nyasaland: A Guide to Prospective Settlers. By J. S. J. McCall. Pp. 85. (Zomba, Nyasaland: The Government Printer, 1920.)

It is greatly to be regretted that the late Mr. McCall did not long survive his promotion from the post of

Director of Agriculture in Nyasaland to the corresponding directorship in the newly acquired Tanganyika Territory. His little book is a useful summary of practical information on cotton and tobacco growing in Nyasaland, and contains just those particulars which experience shows are required by would-be planters with little or no previous knowledge of these crops.

The greater part of the book is devoted to cotton, a crop of which Mr. McCall had much experience. Nyasaland long-staple cotton has gained a high reputation and finds a ready market. A controlling factor in production is transport, and on this point the author expresses the view that "the progress of cotton growing in Africa to-day depends more than ever on railways and mechanical transport. The cultivation of tobacco has become one of the most important planting industries of the Protectorate, and the leaf (Virginian type) is well known in this country. The information given regarding the growing and curing of this crop forms a useful first guide to a subject requiring careful study.

A Popular Chemical Dictionary: A Compendious Encyclopaedia. By C. T. Kingzett. Second edition. Pp. viii+539. (London: Baillière, Tindall and Cox, 1921.) 21*s.* net.

THE first edition of this useful book has been exhausted in less than one year, thus proving that it filled a vacancy in chemical literature. A careful perusal of the new edition shows that much new material has been added which enhances considerably the utility of the book. In particular the chief constants of most of the chemicals named have been added, and the work now forms a handy and popular book of reference embracing in one moderately sized volume a mass of up-to-date information on practically every branch of chemistry and allied sciences.

The information is imparted in a clear and interesting manner, freed so far as possible from technicalities. Consequently any one wishing to ascertain the meaning of a term or definition, or the nature of any material or subject in the scope of chemistry or mineralogy, will find without difficulty and within a few seconds the information required—information which is often difficult to lay hands on immediately when embedded in the pages of a large text-book.

G. M.

The Adjustment and Testing of Telescope Objectives. Third edition. Pp. 123+3 plates. (York and London: T. Cooke and Sons, Ltd., 1921.)

THIS volume is the third edition of a book first published in 1891. The favourable reception accorded to the earlier editions, and the extent of their circulation, have encouraged the publishers to re-issue the work with the amplifications necessary to bring it up to date.

The book deals with the simplest and most effective means of detecting flaws in telescope objectives, as well as the various maladjustments and imperfections of mounting, which may prevent an observer from obtaining the best results from his telescope. Different types of objective are treated separately, a special section being devoted to the Cooke triple photo-visual objective. The points to which attention is given include squaring-on, achromatism, astigmatism, spherical and zonal aberration, mechanical strains, and other smaller, but equally important, matters. There is also a short chapter on the general treatment of objectives. The volume concludes with reprints of three papers by Mr. H. Dennis Taylor, originally presented to the Royal Astronomical Society, dealing with achromatism and the secondary colour aberrations of refractors.

The book is very clearly written, and should prove of great use, not only in detecting faults in imperfect objectives, but also in enabling an observer to determine whether defects in star images are due to the objective or to the manner of its setting. It should appeal especially to the amateur astronomer possessing a small refractor. The directions for testing and adjustment are of the simplest possible character, and involve keen observation rather than mechanical skill.

The publishers have done a great service to astronomy in preparing such a useful little book.

Bibliographia Agrogeologica: Essay of a Systematic Bibliography of Agro-Geology. By Adolf Wulff. (Mededeelingen van de Landbouwhoogeschool en van de Daaraan Verbonden Instituten, Deel 20.) Pp. iv+285. (Wageningen: H. Veenman, 1921.) 4·50 florins.

THE study of the soil has developed so rapidly in recent years that no student can keep pace with the output of papers, nor can the best card index of an individual worker be relied upon as being complete. The necessity for such adventitious aid as is afforded by a bibliography has long become pressing, and this is now supplied by Dr. Adolf Wulff. No fewer than 3300 titles are given, the papers being drawn from more than 600 journals, and the list goes up to November 1, 1919. A satisfactory classification is adopted, so that the student will have no difficulty in finding his way through the bibliography even if he has to consult it only occasionally.

Although the title suggests to English ears only the geological or mineralogical side, the index covers the whole ground dealt with in this country by soil investigators, including soil organisms, soil organic matter, and the relations of soil to the growing plant. The English is remarkably free from errors, and the few misprints will cause no difficulty.

Prof. J. van Baren contributes an interesting discussion on soil problems, bringing together a considerable amount of work which is little known, and forming a useful introduction to the whole volume. Altogether the book is one which can safely be recommended to students and investigators in the subject.

E. J. R.

Patents and Chemical Research. By H. E. Potts. Pp. x+198. (Liverpool: University Press, 1921.) 8*s.* 6*d.* net.

A PATENT, like any other form of contract, depends very largely for its value upon the skill with which it has been drawn up. The form of wording, in fact, may be quite as important as the subject-matter.

Particularly is this so in the case of a patent for a chemical invention, where the scope of the monopoly must be defined in chemical terms and generally without reference to drawings. Clearly, then, it is to the advantage of the patentee to obtain the fullest legal co-operation in drafting the specification for a chemical invention.

Mr. Potts makes this his theme, and in the major portion of his book he develops it by laying down the principles upon which to construct a chemical patent that will procure maximum protection consistent with security against possible infringement or invalidation. His observations should be distinctly helpful both to the research worker in industrial chemistry and to the patent agent, though they tend perhaps to exaggerate a little the function of the latter. Whether, for instance, the patent expert would be capable of diagnosing chemical problems to the extent indicated in chap. 3 is rather open to doubt.

But there can be no question of the author's grasp of the fundamentals of patent law; the discrimination with which he has selected his leading cases when discussing the validity of patents demonstrates this. On the business aspect of patents, too, the author's views are well worthy of attention, especially as regards their value, individually and collectively, in commercial warfare. E. J.

Astronomical Photography for Amateurs. By H. H. Waters. Pp. iv + 93 + v plates. (London: Gall and Inglis, n.d.) 6*s.* net.

AMATEURS possessing small telescopes may, with the means at their disposal, secure good astronomical photographs, and the volume under notice is an elementary handbook intended to explain in a simple manner how good results may be achieved. The book does not go beyond this stage, so that none of the many uses to which astronomical photographs may be put are touched upon.

It is to be regretted that the amateur's share in photographic methods of observation should be regarded as being confined solely to obtaining pictorial records. But, even accepting this limitation, there is much that the amateur may do with telescopes of small aperture. As an instance of what can be accomplished with a small instrument in the hands of a skilled observer, it may be mentioned that many of Prof. Barnard's superb photographs of the Milky Way were secured with a small lens of less than 2-in. aperture. To amateurs desirous of attempting something in this direction, but hesitating through lack of experience and for want of a guide, this book can be recommended. It is written by one who has had some success in this field, and is full of practical hints and directions as to the methods of working, the type of camera necessary, and the exposures and apertures most suitable for photographing various objects. This is just the sort of book which a beginner requires. It includes five plates with reproductions of astronomical photographs obtained by the author. These are printed on a paper of poor quality, with the result that they are practically useless as indications to the beginner of the results which he should be able to obtain. H. S. J.

Philosophy and the New Physics: An Essay on the Relativity Theory and the Theory of Quanta. By Prof. L. Rougier. Authorised translation from the author's corrected text of "La Matérialisation de l'Energie" by Prof. M. Masius. Pp. vi + 159. (Philadelphia: P. Blakiston's Son and Co., 1921.)

La Matière et l'Energie: Selon la Théorie de la Relativité et la Théorie des Quanta. Par Prof. L. Rougier. Nouvelle édition, revue et augmentée. Pp. xii + 112. (Paris: Gauthier-Villars et Cie, 1921.) 9.50 francs.

THE French title is a better indication than the English of the contents of this little book. The only philosophical question discussed at any length is that of the relation between matter and energy, regarded as an extreme example of the fundamental problem of a substance and its properties. By far the greater part of the space is devoted to a simple exposition of the theory of relativity and the quantum theory, which is as well suited for those whose interests are primarily scientific as for philosophers. The exposition is quite adequate, but it is not superior to all others of the same scope. The author has not solved the insoluble problem of giving a true account of mathematical theories without assuming familiarity with the mathematical ideas from which they derive their value and meaning; but he has succeeded in avoiding the distortion of meaning that is frequently a result of such attempts. We can recommend the book to any one with philosophical inclinations who wants to make one more attempt to "understand Einstein," but we are not sure that it was worth translation. However, the translator has done his work, except in the title, with unusual competence.

Personal Beauty and Racial Betterment. By Prof. Knight Dunlap. Pp. 95. (London: Henry Kimpton, 1920.) 6*s.* net.

PROF. DUNLAP'S essay on racial betterment consists of two parts. In the first he analyses the elements which go to make up the ideal of personal beauty as a basis of sexual selection; in the second he deals with its conservation as a means to the improvement of the race. Personal beauty, he maintains, on the negative side is the absence of deformity and of deviation from the accepted type towards that of an inferior race, while on the positive side it is the sign and expression of the *potentiality* of the individual, not in his own interests, but in the interests of the species. Prof. Dunlap meets possible objections that his view of the factors making for racial betterment is entirely physical by maintaining that that is the primary ideal essential for "the attainment of ultimate ideals." This is somewhat vague, but apparently he means that mental and moral qualities may be neglected in sexual selection without detriment—a somewhat large assumption. He discusses the question of the unfit and the desirability in their case of sterilisation, as well as the various causes operative in checking the fertility of those who are best fitted to perpetuate the race. Though he maintains that some fundamental reform is necessary and cannot long be delayed, he himself has no practical programme to propose.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of rejected manuscripts intended for this, or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Magnetic Model of Atomic Constitution.

THE following preliminary description of a new magnetic model atom is given on account of the remarkable coincidence between the results we have obtained experimentally and the views which Dr. Aston has put forward with regard to the atomic constitution of certain of the lower elements.

An attempt has already been made by Sir J. J. Thomson to draw a parallel between atomic structure and the arrangements into which Mayer's magnets group themselves; but this parallelism suffered from the fundamental flaw that there was no numerical relationship between the strength of the central pole and the united strengths of the floating magnets. In order to have a true parallel, it is essential that the strength of the central pole should increase *pari passu* with the number of magnets afloat at one time; for only in this way can a "magnetic neutrality" be obtained which will represent the electrical neutrality of the atom.

In our preliminary work we achieved a close approximation to this state of affairs by using a series of equal magnets. A single magnet was fixed vertically at the bottom of a lead tank filled with water, above the surface of which a second vertical magnet was held in a glass tube. On the water surface, a third vertical magnet was floated by means of a cork disk. All the magnets had their north poles upward. Since both poles of a floating magnet repel those of another floating magnet, it is necessary to have two fixed magnets for each floating one, in order to establish neutrality. When two floats are in the dish, two magnets are placed at the bottom and two magnets in the glass tube, and so on. In this way, the strength of the central pole is always exactly equal and opposite to the combined powers of the floating magnets.

When this arrangement is tested with numbers of floating magnets corresponding to units of atomic weight in the various elements, the following results are obtained. The magnets arrange themselves into two sharply defined and clearly separated groups, the central one of which may for convenience be termed the nucleus, whilst the second group may be named the ring. In the table below are the experimental results showing the distribution of the magnets into the two groups:—

Magnets.	In Nucleus.	Total minus Nucleus.	Corresponds to
1	1	0	Hydrogen.
4	2	2	Helium.
6	3	3	Lithium-6.
7	4	3	Lithium-7.
9	5	4	Beryllium.
10	5	5	Boron-10.
11	6	5	Boron-11.
12	6	6	Carbon.
14	7	7	Nitrogen.
16	8	8	Oxygen.
19	10	9	Fluorine.
20	10	10	Neon.

Inspection will show that this series of groupings corresponds exactly to the suggestions put forward by Dr. Aston. He regards each unit of atomic weight as a proton carrying one positive charge; and the atomic number of the element is, as Prof. Soddy suggested, the algebraic sum of the positive and negative charges in the atomic nucleus. In the new atomic model, it will be seen, the systems arrange themselves spontaneously so as to form a perfect analogy to the hypothetical atomic structures. Thus in the case of Boron-10 the central pole contains ten magnets; five of these are "neutralised" by the five floating magnets of the nucleus, leaving a net "charge" of five, which is the atomic number of boron. In the case of Boron-11 there are eleven magnets in the central pole; six floating magnets "neutralise" six of them, leaving free five—the atomic number of both isotopic forms of boron.

All the known elements and isotopes in the series find their exact parallel in these magnetic models; and the coincidence, if it be merely coincidence, is certainly surprising.

It should be pointed out that hydrogen is anomalous, since obviously a single magnet cannot simultaneously form part of two groupings, nucleus and ring. If the floating magnet in this case be reckoned as a ring magnet instead of a nuclear one, then hydrogen would have the atomic number 1.

It seems worth while to point out that the number of magnets in the ring is always equal to the maximum valency of the element plus two units; and the occurrence of two magnets in the ring of the system corresponding to helium suggests that all the eight elements up to fluorine are built up with two residual non-detachable electrons in the ring. In the case of neon, the non-detachables evidently number 10; and this suggests a connection with the Rydberg series $2(1^2+2^2+2^2+3^2\ .\ .\ .)$, which evidently has some connection with atomic structure.

It appeared of interest to examine the cases of the atomic weights 2, 3, 5, and 8, which have at present no corresponding elements. With two floating magnets, one forms the nucleus and the other the ring group, which gives an atomic number 1. This substance would therefore by analogy be an isotope of hydrogen with an atomic weight 2. With three magnets, one again forms the nucleus, with two others in the ring: this corresponds to the atomic number 2, so that the element, if it exists at all, may be an isotope of helium. Five magnets give a system of two in the nucleus and three in the ring—an isotope of lithium. In the case of eight magnets there are two possible groupings, almost equally stable. Four in the nucleus and four in the ring would correspond to an isotope of beryllium. Five in the nucleus and three outside is the analogue of a fourth lithium isotope. These two groupings would be isobaric systems.

It would occupy too much space to discuss the regularities of the magnetic groupings within the nucleus, but one point of interest may be mentioned. In the case of Boron-11 and carbon, both nuclei contain six magnets arranged in two pairs of concentric triangles. In view of the general resemblance in physical characteristics between boron and carbon, and especially of the fact that in its hydrides boron is quadrivalent like carbon (yielding B_2H_6 like C_2H_6 and not BH_3 as might be expected from its position in Group III.), this peculiarity seems not without meaning.

We propose to extend this investigation immediately with improved apparatus which we hope will surmount some of the obvious experimental difficulties in the case of more complex systems.

Queen's University, Belfast.

Nature of Vowel Sounds.

THE following observations as to the nature of the vowel sounds of a single voice (my own)—details of which form the subject of a separate communication to the journal of the International Phonetic Association—may be of interest.

The sounds were observed by ear, first, for the whispered vowels, and afterwards with a larynx note superimposed. In the whispered series it was found that each of the separate vowels was characterised by *two* resonant notes, an upper component ranging from about ♯d″ (608~) to e‴ (2579~), and a lower component ranging from ♯d′ (304~) to ♯a″ (912~).

The upper components are produced in a manner analogous to that of whistled notes, and their pitch is mainly controlled by the distance of the tongue from the palate and teeth. The same note may be produced with almost any degree of opening of the mouth; about one octave of the scale can be produced—through the nose—with the mouth closed altogether. These notes, for convenience, are referred to as "whistle notes."

The lower components appear to depend, like the pitch of a Helmholtz resonator, largely on the area of the mouth opening—they are referred to as resonator notes.

The two series are independent of each other, so that, for example, an ascending scale of resonator notes and a descending scale of whistle notes may be produced (whispered) simultaneously.

The characteristic whistle and resonator notes for each vowel sound are not absolutely fixed (for an individual voice), but may vary in some cases over as much as 5 semitones without loss of the vowel characteristic.

The ranges of "neighbouring" vowels often overlap, so that two different vowels may have the same whistle or resonator note, but in such cases the other component will be substantially different.

In one or two cases, such as "ii" (eat) and "i" (it) the ranges of *both* components overlap, and the difference between these vowels may be produced in some cases mainly by difference of stress.

When a larynx note is added—as in singing or talking—the pitch of the resonator note does not appear to be affected at all by variations of pitch of the larynx note.

The whistle notes generally are not affected, so long as the pitch of the whistle note in question differs sufficiently widely—say by 2 to 3 octaves—from that of the larynx note.

As the pitch of the larynx note is further raised towards that of the whistle note, the latter tends to adjust itself or "draw" towards the nearest harmonic of the larynx note which lies within it's characteristic range for the vowel in question.

Thus, if a chromatic scale be sung to a given vowel sound, the resonator note will remain constant, but when the note sung approaches within say 2 octaves of the whistle note, this latter may be heard to alternate between or jump from one to another of 3 or 4 neighbouring semitones at each change of pitch of the larynx note.

This last phenomenon has, I find, been already observed by Mr. Perrett.

From these observations it would appear to be possible to make an exclusively acoustic classification of the vowel sounds depending on the range of their whistle and resonator notes respectively.

Protective Colloids—A Pretty Lecture Experiment.

As the result of a large number of experiments carried out in the Chemistry Department of this School by Messrs. Vallance, Dennett, Trobridge, Hammond, and Tidmus in conjunction with the writer, it appears to be a general law that protective colloids or organic emulsoids tend to retard the velocities of such reactions, whether chemical or physical, as involve a change of state in one or more of the components.

Thus it is found that the rates of solution of metals in acids, of corrosion in neutral media, of solution and precipitation of salts, of replacement of one metal by another, as, for example, in the familiar lead-tree experiments, etc., are all retarded by protective colloids. In many cases the rate of retardation conforms to the requirements of the adsorption law. Details of these experiments will be published in due course elsewhere.

A very pretty lecture experiment illustrating this retardation is afforded by the precipitation of mercuric iodide on addition of the chloride to potassium iodide. If this is effected in fairly dilute aqueous solution, the unstable yellow form is first precipitated and rapidly turns from orange to red as it becomes converted to the more stable variety.

If, however, the reaction is carried out in the presence of gelatin, say one per cent., the liquid first turns momentarily yellow, due to the formation of colloidal mercuric iodide, then becomes turbid, and a beautiful canary colour develops, which remains practically unchanged for half an hour or more, according to circumstances. Only very slowly does it change to the red polymorph. The protective colloid retards the growth of the yellow particles. Sunlight accelerates the change markedly. With the aid of the ultramicroscope ($\frac{1}{12}$th inch oil immersion) these changes may be seen beautifully. Drops of gelatin and dilute potassium iodide are mixed under the coverglass and the ultramicroscope focussed as usual. A drop of mercuric chloride solution is brought to the edge of the coverglass and is drawn under by capillary action. The field of the ultramicroscope becomes swept with a stream of luminous particles moving with dazzling velocity—the Brownian movement of the colloidal mercuric iodide. The velocity slows down as the particles increase in size, until the colloid range has been passed, and in a few minutes a fine precipitate is obtained evincing scarcely any movement.

A Problem in Economics.

MANY economic applications of meteorology depend upon the use of forecasts in deciding whether or not to incur expense by taking precautions against some particular phenomenon which would cause damage. A good example is provided by forecasts of ground temperature in deciding whether to pay men to spread sacking over newly-laid concrete road surfaces which would be injured by frost. In the simplest form of such problems the three possible lines of action are (1) to take precautions only on occasions when the phenomenon is forecasted, (2) to take precautions on all occasions, (3) to take no precautions at all. It is of interest to examine the circumstances under which (1) is the most economical line of action.

Let a be the cost of precautions against an event whose probability is P and which will cause damage b if it occurs in the absence of precautions. Suppose the forecast to take the form of a plain "Yes" or "No," and let p be the probability that an occurrence of the event will be preceded by a forecast of "Yes."

With an unbiassed and experienced forecaster it may be assumed that in the long run "Yes" occurs among the forecasts about as frequently as the event occurs. In a large number n of trials, "Yes" will therefore be forecasted on Pn occasions and the expenditure on precautions will be $a \,.\, Pn$.

The event will occur on Pn occasions of which $p \,.\, Pn$ will have been forecasted. The remaining unforecasted occasions will number $Pn(1-p)$ and will entail an expenditure of $b \,.\, Pn(1-p)$ by damage. The total expenditure will therefore be

$$a \,.\, Pn + b \,.\, Pn(1-p). \qquad \text{(I.)}$$

The cost of the forecasts is assumed to be negligible in comparison with a and b.

If precautions are always taken the expenditure will be

$$a \,.\, n. \qquad \text{(II.)}$$

If precautions are never taken the expenditure will be

$$b \,.\, Pn. \qquad \text{(III.)}$$

We have now to compare the amounts involved by I., II., and III. and see which is the least.

I. may be written $b \,.\, Pn - (b \,.\, Pn \,.\, p - a \,.\, Pn)$.

The condition for I. to be more economical than III. is therefore

$$b \,.\, Pnp - a \,.\, Pn > 0$$

or

$$p > a/b.$$

That is to say, the probability of a correct forecast must be greater than the ratio of precautionary expenditure to possible damage. Unless forecasts are very bad or precautions very expensive this condition will be very easily fulfilled.

The condition for I. to be more economical than II. is

$$b \,.\, Pn(1-p) < a \,.\, n(1-P),$$

which expresses the fact that the loss due to possible damage must be less than the saving through omission of precautions. This may be written

$$1 - p < (1/P - 1) \,.\, a/b. \qquad \text{(IV.)}$$

With given values of P, a, and b, IV. sets a limit to the allowable error in forecasting. For example, suppose the chances of the event are even, that is $P = 0{\cdot}5$, the following results are obtained for the limiting values:

$a/b=$	0·01	0·05	0·10	0·20
$p=$	0·99	0·95	0·90	0·80

If the probability of a correct forecast is not above 0·90 it is therefore disadvantageous to base precautionary action on the forecasts unless it costs more than 1*l.* to save 10*l.* worth of damage.

With lower probability of the event things become much more favourable for (1). Thus suppose $P = 0{\cdot}25$ (chances 3 to 1 against the event) we obtain the following results:

$a/b=$	0·01	0·05	0·10	0·20
$p=$	0·97	0·85	0·70	0·40

If in this case the probability of a correct forecast is 0·90 and $a/b = 0{\cdot}10$, the expenditure involved per 100 trials, 1*l.* being the precautionary expenditure, works out as follows:

Taking no precautions	250*l.*
Taking precautions on all occasions	100*l.*
Taking precautions only when the event is forecasted	50*l.*

In practice, the forecaster, being aware that the object of the forecast is to avoid loss by damage, would be biassed in favour of forecasting the event and would only forecast "No" when the odds were considerably against an occurrence. Such a bias would tend to increase p, which was defined as the probability that an occurrence of the event would be successfully forecasted. Against this we would have to set an increased expenditure through needless precautions, and if the forecaster were too cautious this might outweigh the gain resulting from a decrease in unforecasted occurrences. A moderate degree of bias would, however, obviously result in a gain in most cases.

In practice, therefore, the financial results of utilising weather forecasts are likely to be even better than those calculated above.

There is reason to believe that the commercial possibilities of weather forecasts are not fully appreciated. These calculations will serve to show that considerable gain may result from their utilisation, allowing a reasonable margin of error in the forecasts.

E. G. BILHAM.

Age Incidence of Influenza.

THE explanation given by Miss A. D. Betts (NATURE, February 23, p. 240) has always seemed to me an obvious and adequate one. The reply of "The Writer of the Article," that follows it, is admirably clear, and therefore helpful; but I think it really supports the explanation it ostensibly opposes.

Influenza is clearly a disease the incidence and severity of which depend more on the man than on the germ. Some people (apart from the intensive infection and exhaustion of overcrowding and nursing) seem practically immune to it. But all such immunity is probably partial and relative. The successive milder attacks, sometimes not called influenza, that follow a well-marked attack show that the patient is not immune; and any relative immunity is probably largely due to these later successive attacks being treated in time.

In the same way the degree of immunity induced by preventive inoculation is, like other immunity, partial and relative. The inoculated may hope, at least for a time, for substantially increased resistance to infection (but not absolute immunity no matter how intense the infection), and for slighter and briefer attacks if they catch it.

Further, all such relative immunity, if originally present, tends to be destroyed and the severity of the disease and its associated complications increased by exhaustion, whether due to virtuous and patriotic overwork or to vicious dissipation. I do not therefore oppose point (4) of "The Writer of the Article," which is not, however, in dispute here.

But as regards his other three points—

(1) Under end-of-war conditions our young people with unselfish patriotism worked to exhaustion, and largely under conditions involving intensive infection; and as a secondary factor had inadequate food in health and when ill. Again, working as they did largely away from home, the dangerous work of nursing them fell largely on those of their own age, and not, as in normal times, on their parents and elders.

The latter, on the other hand, were not only spared the exhaustion and intensive infection of nursing them, but the "rationing," so trying for the young, was good for us older people, to whom habitual over-eating and drinking is apt to be one of the chief causes of exhaustion and consequent liability to disease, at an age when we should be most immune.

Doubtless the aged were hard hit by the sorrows of the war, which in the end shortened the lives of many; but I take it that, except in the countries actually invaded and ravaged by the enemy, war conditions did not make them more liable to influenza.

(2) Observations on influenza in boarding schools show that those boys who do not readily catch it, and, under normal home conditions, would escape probably entirely, if exposed long enough to the intensive infection of crowded rooms at school, succumb in the

end. This explains the attacks on older people in the later phases of the waves of the war-end epidemic. Their immunity was relative, not absolute.

(3) All European countries, neutral as well as belligerent, were greatly upset and tried by the war; and N. America (Canada and U.S.A.) was belligerent.

GERARD W. BUTLER.

Candahar, Yorke Road, Reigate, Surrey.

Calcium Carbide and the Board of Trade.

THE decision of the Board of Trade Referee that calcium carbide is not a synthetic organic chemical is characterised by "H. E. A." (NATURE, February 23, p. 230) as an offence against both chemical tradition and our chemical conscience. "H. E. A." no doubt may claim to be the keeper of the chemical tradition and conscience of organic chemists, but I should like to dissociate myself personally from his custodianship. How any one can regard calcium carbide, a substance that gives calcium oxide as its sole solid product when moistened with water, as an organic chemical, or an electric furnace operation as the fundamental synthesis of organic chemistry, I cannot understand. What do they know of organic chemical synthesis who only the syntheses of organic chemists know?

FREDERICK SODDY.

PROF. SODDY is a trifle impetuous: my reference to Hazlitt was not out of place, it seems. If I follow my critic, as only a small heap of solid phosphate of lime will be left of me when I am burnt, I am not organic. Granted that calcium acetylide (carbide) gives lime when wetted, it is a little surprising that the putative father of *Emanation* and the first to make clear the significance of helium should attach no importance to the escaping gas. If a man have a wooden leg, he is none the less counted a man, I believe. Now, when zinc ethide is started swimming in water, it leaves behind it its leg, as it were, in the form of zinc oxide, just as carbide does, though in the form of lime; yet the ethide ranks as one of the most honourable of synthetic organic chemicals: why discard the carbide?

One purpose of my article was to direct attention to our lack of logic when using words. Prof. Soddy's comments are but proof that the need to put considered meaning into our words *is* with us. I was led to respect Trench before reading science: in consequence, I have all my life had my attention drawn to words. The term organic has never had any "organic" or vital significance, in chemistry, in Prof. Soddy's lifetime. Thinking chemists have long and logically attached an entirely conventional meaning to it. Before Prof. Soddy was born, I wrote a text-book entitled an "Introduction to the Study of Organic Chemistry," which had as subsidiary title "The Chemistry of Carbon and its Components." I was but adopting a definition put into my hands by my chemical grandfathers. Both carbon and carbonic acid were considered. I would class not only coal but even limestone among "organic compounds."

In conclusion, let me say that the proceedings under the Act are becoming more of a scandal every week. The latest riddle asked is, "When is a chemical not a chemical?" "When it is used as a foodstuff," being the suggested answer. The position of disputants is that defined centuries ago in "Hudibras":

> They're catched in knotted law, like nets;
> In which when once they are imbrangled,
> The more they stir, the more they're tangled,
> And while their purses can dispute,
> There's no end of th' immortal suit.

From beginning to end, every proceeding connected with the Act has been "unscientific." H. E. A.

The Hormone Theory of Heredity.

I SHOULD be much obliged if you would allow me to correct in NATURE, which is, I believe, widely read in the U.S.A. as well as in this country, the erroneous account of my hormone theory of heredity given by Prof. T. H. Morgan in his memoir on Secondary Sexual Characters, Carnegie Institution, No. 285, 1919. At that date Prof. Morgan could only have known the account of my theory in my paper in the *Arch. f. Entwicklungsmechanik*, 1908. His description of my views is contained in the following two quotations from his memoir: (1) "He imagines these hormones to be collected in the germ cells and transmitted to the next generation, where their presence contributes to the further development of the special region (when it develops) that corresponds to the region in its parent in which the hormone was made." (2) "His special appeal to the hormone theory makes use of that theory in a way to which it was never intended to be put, by assuming that an internal secretion formed in one organ can be stored up in another organ, egg or sperm, an assumption not only unsupported by any evidence, but, as I have stated, quite foreign to the hormone theory."

The theory suggested by me in 1908, and put forward in my recent book, "Hormones and Heredity," is that the increased amount of hormones or waste products given out by a structure in which hypertrophy has been caused by external stimulation, may stimulate the determinants or factors corresponding to that structure in the gametes, and so cause some degree of inherited hypertrophy in the next generation. One quotation from my 1908 paper will prove this:

"At the same time the hormone from the incipient antler stimulates the determinants in the gametes. . . . If the stimulation of the determinants is repeated for an indefinite number of generations the congenital tendency to the hypertrophy will become very strong."

The idea of stimulation of a determinant or factor, which may be as Prof. Morgan maintains a part of a chromosome, is very different from the storing up in the gametes of hormones derived from parts of the soma, and for this latter idea I disclaim all responsibility.

J. T. CUNNINGHAM.

East London College, March 6, 1922.

Neon Lamps.

IT does not seem to be generally known that neon lamps, for which many applications can be found in a physical laboratory, are now obtainable very cheaply. They are made to fit an ordinary holder, and contain moderately pure neon (usually somewhat contaminated with mercury) at low pressure. The electrodes are of nickel and are made in various shapes according to the purpose for which the lamp is intended, but they are sufficiently close together for the lamp to run at ordinary supply voltages (down to 100 v.). They are particularly useful for stroboscopic measurements; in this case the lamp is used to illuminate the disc, and may be run from the secondary of an induction coil the primary of which is in series with an electrically maintained tuning-fork.

Another application is to the detection of oscillating P.D.'s in connection with a Fleming cymometer and similar experiments. Possibly, too, they may be of service in spectroscopic work where the dispersion is small or the exposure long, as the lines are not too numerous and their wave-lengths are in many cases very accurately known. Their great advantage over the ordinary neon vacuum tube is of course their cheapness; the last one I purchased cost 3*s*. 9*d*.

W. E. CURTIS.

Wheatstone Laboratory, King's College, W.C.2, March 6.

Photosynthesis.

By PROF. E. C. C. BALY, F.R.S.

PHOTOCHEMICAL reactions, more particularly those in which highly endothermic syntheses take place, have generally been considered as something apart from the ordinary chemical reactions of the laboratory, and, indeed, have at times savoured of the mysterious for the reason that they seemed to be impossible of realisation *in vitro*. Recent work, however, on the energy changes involved in chemical reaction has shown that there is no inherent mystery in photosynthesis, and that all reactions, including those of photochemistry and catalysis, are completely analogous and obey the same laws. Every complete reaction consists of three separate stages, with each of which is associated its characteristic energy change. In general, molecules in the free state exist in a phase which is non-reactive, and in order to carry out any reaction it is first of all necessary to bring them into a reactive phase. This, which is the first stage of the reaction, requires that a definite amount of energy should be supplied to each molecule, the amount necessary being the difference in energy contents of the initial phase and the particular phase necessary for the reaction in question. Each phase of a given molecule differs in energy content by a fixed quantity of energy characteristic of that molecule, which is called the molecular quantum of energy. It follows, therefore, that the amount of energy necessary to activate each molecule in the first stage of the reaction is exactly one or more molecular quanta.

The second stage of the reaction is the atomic rearrangement whereby new molecules are produced, and it is this stage, and this stage alone, which is represented by the equation of the reaction.

The third and final stage is the change in phase of the newly synthesised molecules, whereby they pass into their normal and non-reactive phases. These last two stages are both accompanied by an escape of energy, and in each of them the amount of energy lost per molecule is exactly one or more molecular quanta characteristic of the new molecules. If the sum of the amounts of energy evolved in the second and third stages is greater than that absorbed in the first stage, the reaction is exothermic; whilst an endothermic reaction is one in which the energy necessary for the first stage is greater than the total amount evolved in the second and third stages.

There are three methods by which the energy necessary for the first stage may be supplied. It may be supplied by a material catalyst, or as radiant energy in the form of heat or light. The action of a catalyst does not arise here, and need only be mentioned in order to guard against any misconception. Many reactions take place in solution without the apparent intervention of the first stage, but in such cases the molecules have been activated by the solvent which functions as a catalyst.

In general, it is a matter of little consequence whether a molecule is activated by heat or light—that is, by infra-red or ultra-violet rays—in view of the known integral relationships that exist between the frequencies at which a molecule can absorb energy. It is a matter of cardinal importance, however, in the case of highly endothermic reactions, in which the increment of energy required for the initial phase change is obviously a large number of molecular quanta. When a molecule absorbs energy at its principal frequency in the infra-red, it absorbs it in terms of its molecular quantum; but if it absorbs ultra-violet light the unit of energy absorbed is a quantum which is an integral multiple of the molecular quantum, the multiple depending on the phase in which the molecule exists. One single quantum of energy absorbed at the characteristic frequency in the ultra-violet is always sufficient to activate a single molecule for any reaction, however endothermic this may be.

An endothermic reaction, in the first stage of which each molecule requires a large number of molecular quanta to activate it, will obviously be very much easier to carry out by exposing the molecules to energy of their characteristic frequency in the ultra-violet, when the absorption of one quantum per molecule is sufficient, than by exposing them to infra-red radiation, when the reaction will not proceed until a specific number of quanta have been absorbed by each molecule. When, as is frequently the case, this specific number is ten or more, it is not surprising that the realisation of the reaction by means of heat becomes impossible from the practical point of view. Such a reaction, however, is readily brought about by the absorption of a single quantum by each molecule at its characteristic frequency in the ultra-violet.

This may be understood more clearly from a specific instance, namely, the decomposition of hydrogen chloride into hydrogen and chlorine. The molecular quantum of HCl is about $5{\cdot}7 \times 10^{-13}$ erg, whilst the quantum absorbed at the ultra-violet frequency is about $9{\cdot}7 \times 10^{-12}$ erg, which is seventeen times as large. The activation of an HCl molecule so that it may decompose requires seventeen molecular quanta, and this may readily be brought about by exposing the gas to radiant energy of the wave-length 203 $\mu\mu$, when the absorption of a single quantum per molecule is sufficient. In order to bring about this reaction by heat, it will be necessary for each molecule consecutively to absorb seventeen molecular quanta, without losing any by radiation during the process, before it can decompose. The preparation of hydrogen and chlorine from hydrogen chloride is therefore very difficult to carry out by the aid of heat, but is readily induced by light. Another highly endothermic reaction which may be realised photochemically is the synthesis of formaldehyde from carbon dioxide and water, for it has been shown that under the influence of light of wave-length 200 $\mu\mu$ the reaction takes place according to the equation $CO_2 + H_2O = CH_2O + O_2$. These two examples are sufficient to show that whilst there is no essential difference between any two chemical reactions, those that are highly endothermic can be realised in practice only by photochemical stimulation.

The photosynthesis of formaldehyde from carbonic acid is of great importance, because it undoubtedly forms the first step in the formation of the many complex substances produced in the living plant. Some recent work in Liverpool on this reaction has thrown

light on the mechanism utilised by the living plant in carrying it out, and also on the general problem of the photosynthesis of vegetable products. Although the synthesis of formaldehyde has been carried out photochemically in the laboratory with light of wave-length 200 $\mu\mu$, this is certainly not the case in the plant, for there is present in sunlight no radiation of this wave-length. The plant must in some way carry out the reaction with the absorption of visible light, for it is well known that visible light only is necessary for the photo-assimilation of carbon dioxide. It has been shown experimentally that, if a visibly coloured basic substance be added to the aqueous solution of carbon dioxide, formaldehyde is produced on exposing the mixture to visible light. The coloured substance, being basic, forms a complex with the carbonic acid, and within such a complex the components possess an identical infra-red frequency; that is to say, the molecular quanta of the two are identical. The energy absorbed by the coloured component is radiated at this common infra-red frequency and re-absorbed by the carbonate component. The necessary increment of energy is thus gained by the carbonate component, which is converted into a molecule of formaldehyde and a molecule of oxygen. This type of reaction has been named photocatalysis, the coloured substance acting as photocatalyst. It has been proved that malachite-green, methyl-orange, and *p*-nitrosodimethylaniline act as photocatalysts in this reaction, and in the presence of carbon dioxide give formaldehyde on exposure to visible light.

It has been shown by Willstätter that chlorophyll as it occurs in the plant combines with carbonic acid, and hence there is little doubt that it functions as a photocatalyst. The green-coloured complex absorbs visible light, and the energy so absorbed is transferred to the carbonic acid through the identity of infra-red frequency, with the result that formaldehyde and oxygen are produced. Although this gives a satisfactory explanation of the mechanism by means of which the living plant is able to produce formaldehyde with the aid of visible light alone, the story is far from complete, for there are yet to be considered the formation of carbohydrates from the formaldehyde, and the details of the process whereby the oxygen set free in the photosynthesis is transpired by the plant as gaseous oxygen.

It was shown by Moore and Webster that aqueous solutions of formaldehyde on exposure to ultra-violet light are polymerised to reducing sugars, but no evidence was given of the nature of these sugars or of the wave-length of the light required. It has been shown more recently in Liverpool that the necessary wave-length of the light is 290$\mu\mu$, which at once establishes the fact that the polymerisation is photochemically distinct from the synthesis of formaldehyde. It has also been shown indirectly that the polymerisation of formaldehyde can be photocatalysed; but this is of scientific interest only, since there is no need to postulate such a mechanism in the plant. On exposure to ultra-violet light the formaldehyde molecules are activated, and it is these activated molecules which undergo polymerisation to sugars, since it is well known that ordinary formaldehyde does not polymerise in this way. When the formaldehyde molecules are first produced by photosynthesis they are in the activated form, and may therefore lose energy in one of two ways, either by change of phase to produce ordinary formaldehyde or by polymerisation to give sugar molecules. But it has been proved that the photochemically activated molecules at once polymerise to sugar, and therefore the photochemically synthesised molecules do the same. There is thus no need to consider the activation of the formaldehyde in the plant, for it is already activated when produced. The absence, therefore, of free formaldehyde in the growing leaf is explained by the fact that the photosynthetic process from carbonic acid to sugar takes place without a break. (Baly, Heilbron, and Barker, *Trans. Chem. Soc.*, vol. 119, p. 1025, 1921.)

The mechanism of the process whereby the oxygen, which is produced with the formaldehyde in the photosynthesis, is transpired as gaseous oxygen is one of great importance in view of the energy changes involved. Willstätter has shown that chlorophyll is in reality a mixture of two substances, chlorophyll A and chlorophyll B, and that a molecule of chlorophyll B contains one atom of oxygen more and two atoms of hydrogen less than a molecule of chlorophyll A. Two atoms of oxygen, therefore, are required to convert a molecule of chlorophyll A into a molecule of chlorophyll B, and since this is the exact relation required in the photosynthetic operation it is impossible to believe that it is not utilised. It is in the highest degree probable that a molecule of chlorophyll A combines with a molecule of carbonic acid, and that this complex on exposure to light gives a molecule of activated formaldehyde and a molecule of chlorophyll B. Willstätter hesitates to accept this view, because he found that the ratio of chlorophyll B to A is not altered during photosynthesis; but since he also proved that the velocity of transpiration of the oxygen is equal to that of the absorption of carbon dioxide, this cannot be accepted as evidence. It means only that there is present in the leaf some mechanism whereby the chlorophyll B is deoxidised and reconverted into chlorophyll A. Willstätter has further proved that an aqueous solution of chlorophyll, saturated with carbon dioxide, decomposes on exposure to light, no measurable photo-assimilation of carbon dioxide taking place. This affords an additional proof that there is present in the living plant a mechanism for maintaining the chlorophyll equilibrium.

In the living photosynthetic cell there exist, along with the chlorophylls, two more pigments, carotin, $C_{40}H_{56}$, and xanthophyll, $C_{40}H_{56}O_2$, the relation between the two as regards oxygen being the same as that between chlorophyll A and B. It may therefore be suggested that carotin has the power of reducing chlorophyll B to chlorophyll A, itself being oxidised to xanthophyll. This is supported by Willstätter's observation that the ratio of xanthophyll to carotin is increased during the photosynthetic operation. This increase, though perfectly definite, is not large enough to decrease materially the amount of oxygen transpired.

The complete reaction, $H_2O + CO_2 = CH_2O + O_2$, is highly endothermic, and is accompanied by the absorption of about 150,000 calories per gram-molecule of formaldehyde produced; and it is interesting to note that one quantum of energy absorbed in the

visible region by chlorophyll is not sufficient to induce the complete reaction, since 150,000 calories per gram-molecule is almost exactly one quantum per molecule at $\lambda = 200\mu\mu$. Certain quantitative experiments have shown that a possible explanation of this is to be found in the fact that the carbonic acid is partly activated by combination with the chlorophyll. Alternatively, it is possible that, whilst one quantum of energy at $\lambda = 200\mu\mu$ is required for the complete reaction with the escape of free oxygen, one quantum of visible light as absorbed by the chlorophyll is sufficient to induce the reaction

$$\text{Chlorophyll A} + H_2CO_3 = \text{chlorophyll B} + CH_2O.$$

It is scarcely necessary to point out that either of these alternatives amplifies the principle of photocatalysis as previously defined. In either case the completion of the reaction, whereby the oxygen is abstracted from the chlorophyll B and transpired into the atmosphere, must require a further supply of energy. This second amount of energy is doubtless absorbed by the carotin and xanthophyll, the absorption bands of which lie in the visible region and between those of chlorophyll, so that each can absorb visible light simultaneously and independently. This suggested explanation is now being investigated.

Reference may be made to some other work now in progress at Liverpool which has already given most promising and suggestive results. By the action of ultra-violet light on aqueous solutions of formaldehyde, several hundred grams of concentrated sugar syrup have been prepared. Analysis of this syrup has shown that the sole products of the polymerisation are hexoses, no trace of a triose or pentose having been found. This result is very striking in view of the greater possibility on the kinetic theory of the formation of sugars containing fewer than six carbon atoms. There can therefore be no possible doubt that the sole products of the polymerisation of the activated formaldehyde as photosynthetically produced in the living plant are also hexoses. Not only does this afford a ready explanation of the storage of starch in the chloroplast during the period of photosynthetic activity and its subsequent hydrolysis to hexoses, which are utilised by the plant in later syntheses, but it also establishes the fact that pentoses must be formed from hexoses, possibly through furane compounds; further, it opens the door to most promising theories of the synthesis of other plant products, every stage of which is attractive in its simplicity.

Then, again, there is the question of the production of the various nitrogen compounds in the plant, which is one of considerable interest, since it would seem that the principal source from which the plant derives its nitrogen is potassium nitrate. It is well known that metallic nitrates are readily converted to nitrites by material catalysts as well as by ultra-violet light. Baudisch has shown that an aqueous solution of potassium nitrite and methyl alcohol, on exposure to ultra-violet light, gives formhydroxamic acid, the alcohol first being converted to formaldehyde. This has been confirmed at Liverpool by investigation of the action of ultra-violet light on aqueous solutions of potassium nitrate or nitrite containing formaldehyde, and it has been proved that an activated molecule of formaldehyde combines with a molecule of potassium nitrite according to the equation $CH_2O + KNO_2 = CH(OH):NOK + O$, since the reaction takes place only in the light. It has also been found that if the activated formaldehyde is in excess formhydroxamic acid and hexoses are simultaneously and independently produced. This condition is doubtless that which obtains in the plant, and it may be concluded that the two syntheses take place in the leaf without mutual influence. It is worthy of note that the photosynthesis of formaldehyde and the synthesis of formhydroxamic acid are both accompanied by the setting free of oxygen.

Experiments are also in progress on the reaction between activated formaldehyde and ammonia, and although these are not yet complete, they have already established the great reactivity of activated formaldehyde towards ammonia. Whatever, therefore, may be the starting point on the nitrogen side, potassium nitrate or ammonia, there is no question that, in the presence of activated formaldehyde such as is produced photosynthetically in the plant, compounds are formed in which carbon and nitrogen are united, thus securing the first step towards protein, pyrrole, and alkaloid synthesis.

Finally, one very important deduction may be made. The sole photosynthetic process in the living plant would seem to be the production of activated formaldehyde from carbon dioxide and water. These activated molecules either polymerise to hexoses or react with potassium nitrite or ammonia. Any further reactions are not photochemical except in so far that the first synthesised nitrogen compounds combine with more molecules of activated formaldehyde to give complex nitrogen derivatives.

The Migration of British Swallows.

By Dr. A. LANDSBOROUGH THOMSON, O.B.E.

"Sister, my sister, O fleet sweet swallow,
Thy way is long to the sun and the south."
SWINBURNE.

FROM time immemorial the Swallow (*Hirundo rustica*, Linn.) has been a proverbial type of summer visitor to our northern lands, but age-long familiarity with the fact of its seasonal appearance and disappearance has not served to bring us complete knowledge or understanding: there are many secrets, both matters of fact and questions of interpretation, to which we have as yet no clue. Nevertheless we are in a better position to appreciate the problem than were Gilbert White and his contemporaries, who were obsessed with the idea that hibernation, particularly in regard to this species, might play an important part as an alternative to migration. White was particularly influenced by the frequent phenomenon of the few "early swallows" which appear some time before the main contingents arrive, and are no more seen if wintry weather should recur in the meantime. The theory of hibernation dies hard even to-day, and every now and then some imperfect piece of evidence in its

favour is recorded—cases, for instance, of birds lingering in autumn being overtaken by hard weather and being found in a comatose condition, really moribund rather than dormant. The further idea that the place of hibernation was in the mud at the bottom of reedy ponds was regarded with sufficient seriousness in the time of John Hunter, the famous anatomist, for him to examine it scientifically; with a truly modern appreciation of experimental methods, he confined swallows in a conservatory one autumn, providing them with water, reeds, and mud, and the result naturally confirmed his scepticism.

Nowadays we know enough of migration to have no need to explore alternative theories, but it still remains true that we see migration actually in progress comparatively seldom, although perhaps we do so more often in the case of swallows than in that of most small birds. The writer recalls one fortunate occasion, for example, when he spent the morning of a bright autumn day sitting at the extreme northern apex of the isle of Heligoland watching the swallows coming in over the sea in the teeth of a southerly gale. For hours there was a steady succession of small bands of from half-a-dozen to a score of swallows, all flying low over the sea and coming into sight as they rose to the level of the cliff-tops. All the birds kept to the same course, the stream following the line of the western cliffs and quitting the island again at its south-western corner. Only an occasional bird circled round for a few minutes, and none seemed inclined to break its journey so early in the day in spite of the adverse conditions. But a glimpse of this kind is only seeing in momentary cross-section, so to speak, one tiny rivulet of the great emigratory stream of swallows from Northern Europe.

Much has been learnt, however, by the careful piecing together of observations collected from many different places, notably from the lighthouses and lightships round the British coasts. From these data Dr. Eagle Clarke was able to give us some years ago, in the report of the special committee appointed by the British Association, an elaborate summary of the movements which usually take place in the British area, and more recently this has been supplemented by the labours of a committee of the British Ornithologists' Club. A few early birds may appear in March, but the average times for the arrival of the vanguard of our summer visitant swallows are:—for south-western England the beginning of the first week in April, for Ireland the end of that week, for south-eastern England early in the second week, for south-western Scotland the end of the same, for south-eastern Scotland the middle of the third week, for northern Scotland the fourth week, and for the Orkney Isles the second week of the following month; the main influx usually begins some ten or twelve days later in each case. The earlier dates for the western regions, latitude being equal, are noteworthy, and it appears that the immigratory waves arrive along the whole length of the south coast of England, but first and chiefly on its western half. Before this immigration of our native birds has been completed—at the very end of April—there begin the passage movements of swallows traversing the eastern seaboard of Great Britain *en route* for northern Europe, and these movements may be prolonged until almost the middle of June.

Decided southerly movements within the British area begin towards the end of August, and early in September actual cross-channel emigration sets in and continues for nearly two months, after which only stragglers are as a rule recorded. From the middle of September onwards there is also the return passage of swallows from Northern Europe, and the two sets of movements are not easily distinguishable. There is also a passage movement from Central Europe, first observed by Dr. Eagle Clarke from the Kentish Knock Lightship, the line of flight being roughly from east to west; the existence of a corresponding spring passage on this line has not been definitely established. A very few instances are on record of swallows surviving in this country throughout exceptionally mild winters.

Within the last few years the method of marking birds with numbered aluminium rings has been widely employed in this country, under the auspices both of the magazine *British Birds*, edited by Mr. H. F. Witherby, and of the University of Aberdeen. The proportion of marked swallows recovered is unfortunately very small, for out of 1198 marked during the Aberdeen scheme only five, or 0.4 per cent., were recovered. The *British Birds* scheme, which is still actively in progress, has nevertheless yielded a very interesting series of records for the species, representing a vast amount of energy in marking; 7597 had been marked up to the end of 1920, and 60 (or 0.7 per cent.) have been recovered. A brief summary of the results of this work, taking the published data of the two schemes together, may accordingly be given with advantage.

There are, to begin with, various records of swallows marked as nestlings and recovered within a few miles a little later in the same season, but these are without special significance. The European stages of migration are indicated by records of birds marked as nestlings and reported in their first year, as follows: one marked in Lancashire from the Isle of Wight late in October; one marked in Lancashire from Indre-et-Loire, in the centre of France, in September; one marked in Staffordshire from Charente-Inférieur, south-western France, in October; and one marked in Staffordshire from Brittany in December, but without information as to how long it may have been lying dead before it was discovered. Further, a swallow marked as a nestling in Staffordshire was recovered at Bilbao, northern Spain, in March of the following year.

Four swallows marked as nestlings, all under the *British Birds* scheme, have been recovered in South Africa during their first winter: a Lancashire bird in Cape Province in February, an Ayrshire bird in the Orange Free State in March, a Yorkshire bird in East Griqualand in February, and a Stirlingshire bird in the Transvaal in January. A swallow marked in Staffordshire as an adult, also, was recovered in Natal in December of the second winter thereafter. Mr. Witherby has directed attention to the suggestive fact that all these five records of his are from the eastern portion of South Africa. A swallow marked in Schleswig-Holstein was obtained on migration at Bregenz, on the Lake of Constance; another, marked as a nestling in Overijsel, Holland, was recovered on October 1 of the same year at Tangier, Morocco.

Of great interest, also, are the records which indicate

the return of swallows to their native districts in subsequent summers. Seventeen marked as nestlings have been so recorded, sixteen in the following summer and one in summer two years after marking, the localities ranging from Hampshire to Kincardineshire. Six marked as adults have been similarly recorded, three after one year and three after two years, the localities ranging from Staffordshire to Peeblesshire.

In some of the foregoing cases the return to the same place was very exact—even to the self-same porch or outhouse. In others the place of recovery was a few miles from the place of marking; a swallow marked as a nestling at Beaulieu (Hampshire), for instance, was recovered in the following May at Ringwood, in the same county but 18 miles distant. There are other cases, still to be mentioned, in which swallows marked as nestlings returned in the following summer to parts of the country rather more widely separated from their respective birthplaces, the distances being from Hampshire to Sussex (30 miles), from Hampshire to Middlesex (70 miles), from Stirlingshire to Yorkshire (170 miles), and from County Kildare to County Armagh (75 miles).

Migration of swallows from Great Britain to South Africa is thus clearly established, and it is also now certain that the birds commonly return to the same summer quarters, often with great exactness, in subsequent years. Much still remains to be learnt, and some of this the marking method may give us in time. What route is followed between Great Britain and South Africa, for example, and are the identical winter quarters repeatedly sought out in the same way as breeding-places? Further, how do the migrations of British swallows compare with those of swallows native to other countries: can we, for instance, confirm Dr. Hartert's suggestion that "the most northerly dwellers migrate furthest south, while the breeding birds of the Atlas Mountains probably go only to the oases of the Sahara for the winter"? These questions strike at the very roots of the nature of the migratory instinct, one of the great wonders of the animate world.

Obituary.

Prof. Benjamin Moore, F.R.S.

By the death of Prof. Benjamin Moore, at fifty-five years of age, science has suffered the loss of an original and daring thinker. Moore was born, and studied, in Belfast, and the first degree he took was Bachelor of Engineering. At one time he thought of following that profession. He received a travelling research scholarship, and studied physical chemistry under Ostwald in Germany, and then came to London and studied physiology under Sharpey Schafer. From thence he went to fill a chair at Yale Medical College, but returned a few years later to be lecturer in physiology at Charing Cross Medical School, and at the same time to qualify himself as a medical man—a double task requiring much nerve, energy and courage. Moore was then elected to the newly-founded Johnston chair of biochemistry at Liverpool—the first chair in that subject to be founded in this country. He took a most active share in the development of the Medical School at Liverpool University, and jointly with Mr. Whitley founded the *Biochemical Journal*. He was elected a Fellow of the Royal Society in 1912. In 1914 he accepted an invitation to join the Department of Applied Physiology under the Medical Research Council, and after rendering valuable services to industrial medicine during the War, was elected, in 1918, to the newly-founded Whitley chair of biochemistry at Oxford. There he quickly inspired several of his honour school students to carry out pieces of research work, and all too soon he has passed from thence, the victim of influenza. He took the greatest interest in Public Health, and a State Medical Service, as shown by his book "The Dawn of the Health Age."

Moore was a man of impetuous imagination, conceiving brilliant ideas, and stimulating others by these and his enthusiasm; he was impatient under the necessarily slow accumulation of results required for confirming his ideas—an impatience which sometimes led him to be too hasty in publication, and to subject himself to criticism whereby his spirit was vexed and his energy wasted in controversy. He was perhaps sometimes wild, sometimes wrong, but often the pioneer in visions of great value. To him we owe the first attempts in this country to apply the results of physical chemistry to the intricate problems of biology. The article by Moore published in "Recent Advances in Physiology," edited by L. Hill, and last year elaborated and republished in book form, did much to found the British school of physico-chemical physiology.

Moore was fascinated by the problem of the origin of life, and formed conceptions of the first steps in the evolution of life by the synthesis of inorganic compounds. He was able to show the formation of formaldehyde from CO_2 and H_2O under the influence of sunlight on a commonly occurring substance like iron oxide. This was the beginning of a series of papers on photosynthesis, on which a value higher than at present will probably be set in future time. He recently demonstrated the production in the air of oxides of nitrogen by the action of sunlight, and conceived the assimilation of these when dissolved in rain and dew by the green leaf. He was a pioneer in the work which is now given so much attention among physiologists, namely, on the normal reaction of body fluids and the maintenance of this normality, acidosis, etc.

Tackling the problem of trinitrotoluene poisoning, which was working havoc in munition factories during the War, Moore found that the chief danger was due to the absorption of this material through the skin—a view which met with considerable opposition, and led to controversial strain upon his sensitive nature. This discovery, when fully accepted, enabled thousands of workers to be preserved from poisoning during the War, and saved the country paying out hundreds of thousands of pounds in the settlement of employers' liabilities.

The sudden death, from appendicitis, of Moore's wife, who was devoted to his care, was an irreparable loss to him, and made a vast difference to the happiness and health of his last years. He leaves one son—a chemist in training—and two daughters. L. H.

Dr. A. D. Waller.

We record with much regret the death on March 11, at fifty-five years of age, of Dr. A. D. Waller, director of the physiological laboratory and professor of physiology in the University of London.

M. Camille Jordan.

By the recently announced death of Camille Jordan the mathematical world has sustained the loss of one of its greater modern analysts. Born in 1838 Jordan succeeded Chasles (1881) in the geometrical section of the Paris Academy of Sciences. Later he was given the chair of mathematical analysis at the École Polytechnique, from which he retired a few years ago.

In the earlier part of his career Jordan's mathematical work was mainly geometrical. An important memoir is concerned with polyhedra and the attendant geometry of position. In another paper he obtained the condition that two flexible and extensible surfaces should be applicable to one another without tearing or doubling over. His work on symmetry and displacement-groups anticipated later research on transformation-groups, and has been used in theoretical crystallography.

Jordan left his deepest impression, however, by his work on substitutions and algebraic equations. In his "Traité des Substitutions" he followed up Galois' ideas, obtaining fundamental results on primitive, transitive, and composite groups, and on the composition-factors of a group. These investigations enabled him to settle a question proposed by Abel, *viz.* to decide whether a given algebraic equation is soluble by radicals or not. Other work of Jordan's is concerned with algebraic forms and linear groups of finite order, with their applications to algebraic integrals of linear differential equations.

Some of Jordan's more recent work was on the theory of functions of a real variable. His name will be remembered as the discoverer of *Jordan curves*, the most general curves which cut a plane into two distinct portions.

W. E. H. B.

Current Topics and Events.

The call for economy in the Civil Service has produced a number of letters in the correspondence columns of *State Technology*, the journal of the Institution of Professional Civil Servants, from members who do not belong to the administrative section of the service or to the clerical section from which the administrative is recruited. The object of these letters is to show that great saving might be effected by making better use of the professional, scientific, and technical officers of the service. At present it often happens that progressive scientific development is hampered by the existence of a control without knowledge of the scientific work on which the professional members are engaged. Such a control tends towards a stereotyped system in which each member of the service becomes a mere machine without inspiration or initiative, and to the promotion of clerks into secretaries, deputy secretaries, assistant secretaries, etc., at salaries out of all proportion to the value of their services to the State. From letters in the February number of the journal it appears probable that some of these facts are to be discussed in the daily press in the near future.

The Field Museum of Natural History, Chicago, announces several collecting expeditions. Mineralogists will visit the gem-producing and the gold- and copper-producing districts of Brazil, the silver- and copper-producing districts of Peru and Bolivia, and the nitrate and vanadium deposits of Chile. Fossil vertebrates will be sought in Patagonia, northern Argentine, and Brazil. Zoologists and botanists will be associated in the Sierras of Central Peru and round the sources of the Amazon. Archaeologists will visit the Isthmus of Panama, the State of Colombia, and the Colorado Desert. Dr. Fay-Cooper Cole is to study the races of the Malay Peninsula and to explore the interior of Borneo. Dr. Berthold Laufer proposes to study the aboriginals of Hai-nan, and to make archaeological collections in Fu-kien and Manchuria.

A violent gale traversed the southern portion of England during the night of March 7 and the forenoon of March 8. The storm arrived from the Atlantic and was first experienced on our south-west coasts, whence it travelled across the south and east of England to the North Sea. In the English Channel and at the southern English stations the south-westerly and westerly winds attained hurricane force. At Scilly the wind blew with the velocity of 108 miles an hour at 4 a.m., a speed which has only once previously been exceeded in the United Kingdom, the wind in a gale on January 27, 1920, registering 110 miles an hour in Co. Clare, Ireland. The storm was accompanied in most parts by heavy rains, and the violence of the wind occasioned a large amount of damage.

Under the title "Research Laboratories in Industrial Establishments of the United States, including Consulting Research Laboratories," a Bulletin of the U.S. National Research Council (1921, vol. 3, Part I., pp. 135) has recently been issued. The report gives an alphabetical list of 526 industrial establishments in the U.S.A. having research laboratories, the name of the chief worker, the number of the staff, the nature of the work, and the special equipment, together with a subject classification and index, and a list of the directors of research with addresses. It is a most interesting compilation, furnishing useful details not only of the enormous staffs of such companies as E.I. du Pont de Nemours, Eastman Kodak, Goodyear Tyre, General Electric, and Western Electric, but even of the small laboratories with only one or two workers. It is very plain, however, that the term "Research" has been generously applied, for the vast majority of the laboratories would be modestly referred to in this country as "works laboratories." The equipment catalogued is also quite conventional in most cases, but it is amusing to read that the Edison laboratory has a "large scrap heap from which to rob to build

other apparatus," and some scientific workers may envy the lot of the two members of the staff of a sugar company who have a "candy kitchen" at their disposal. It is flattering to the chemist to find how largely he preponderates in the various staffs, but many an industry would be better served by the co-operation of other scientific workers, especially physicists.

Among the pioneers of the locomotive a high place is deservedly given to Timothy Hackworth, who was born December 22, 1786, and died July 7, 1850. No complete biography of Hackworth has yet been written, and his merits apparently escaped the notice of the compilers of the "Dictionary of National Biography." This rendered all the more welcome the interesting review of his work which Mr. Robert Young, a grandson of Hackworth, gave to the Newcomen Society at the meeting held on March 1. Hackworth's youth was spent at Wylam Colliery, where Hedley built his "Puffing Billy." By 1824 he was sufficiently well-known to take charge of Stephenson's works at Newcastle, and the following year he became engineer and manager of the famous Stockton and Darlington Railway. For this line he built the "Royal George," which definitely asserted the superiority of steam over horse traction, and a year or two later the "Sans Pareil," a powerful competitor with Robert Stephenson's "Rocket" in the Rainhill trial of October 1829. If for nothing else Hackworth deserves recognition for his discovery of the proper manner of discharging the exhaust steam up the funnel so as to create a powerful draught through the furnace. He was, however, far more than a successful inventor. For fifteen years he managed the Stockton and Darlington Railway, and his workshops at Shildon became a training ground for locomotive engineers. He was also a great captain of industry and set an example in his treatment of his workmen. All these matters were touched upon in Mr. Young's paper, and information was given about many of the engines Hackworth constructed, among them being the first locomotive to be sent to Russia, and also the first to be run in British North America.

Prof. B. Brauner, professor of chemistry and director of the chemical laboratory, Bohemian University, Prague, has sent us an article, which we hope to publish in a week or two, on work done by Bohemian men of science during the war and after. He has been a reader of Nature for forty-two years, and has on a number of occasions made original communications to its columns. We particularly appreciate, therefore, the following reference to this journal in an article contributed by him to the leading Bohemian periodical, *Národní Listy*, of December 21 last:—"My favourite reading is the London journal Nature, circulating over the whole world and bringing articles about all acquisitions of the human spirit, from bacteria to the Egyptian 'Book of the Dead,' from the structure of atoms to the structure of the universe. The magnificent work of my teacher Bunsen and of Kirchhoff on spectrum analysis, together with the principle of our Doppler (who lived in Prague), which led us to understand of what and how the stars are formed and how they move; the work of Kekule ze Stradovic, a descendant of the Protestant exiles of Bohemia three hundred years ago, on the structure of matter; photography, Darwinism, theory of evolution, Mendeléeff's periodic system, Röntgen's discovery, Becquerel's discovery of radioactivity and the great chemical and electrical discoveries connected with it, which led to our knowledge of the innermost constitution of the atoms—of all these discoveries and their evolution and progress Nature brings each week the most recent information. Everything described is connected together as a whole and yields a magnificent picture of Nature on the earth and in the universe. It is our religion—reverence to the One Who all this, and also ourselves, created of the original nebula, *i.e.* almost of nothing, and at the same time admiration of the human spirit which investigated and conceived it."

On Wednesday, March 1, there was opened at the British Museum a special exhibition of Greek and Latin papyri presented at various dates by the Egypt Exploration Society. This body (formerly the Egypt Exploration Fund) is celebrating the twenty-fifth anniversary of the foundation of its Græco-Roman Branch, the excavations of which at Behnesa (Oxyrhynchus) and elsewhere have made so many additions to our stock of Greek literature and to our knowledge of the political, economic, and social history of Græco-Roman Egypt; and it is in honour of the anniversary that the Museum is arranging its exhibition. A guide-book to the exhibition, with introduction, detailed descriptions of the papyri shown, a preface by Sir Frederic Kenyon, and one photographic facsimile, is being published by the Society, and will be on sale at the Museum, price 1s. The exhibition, which will be found in the MSS. Saloon, Case A, includes many interesting papyri of various kinds, selected to illustrate the wide range of papyrological discovery. There are examples of famous additions to Greek literature, like the Pæans of Pindar, the poems of Cercidas, and the Oxyrhynchus historian; theology is represented by the Sayings of Jesus; and the economic and social life of Egypt finds illustration in many non-literary documents, several of them rich in human interest.

In the middle of January the first issue of a new technical publication appeared entitled *Oil Engineering and Finance*, a journal intended for the producer and user of petroleum and also for the investor. A feature of the enterprise is the division of the paper into sections, each dealing with a particular phase of the industry, such as oilfield development, oil refining, fuel and lubricating oils, oil fuel, heavy oil engines, and the home oil industry, each section being under the editorship of a specialist in the particular branch under discussion. The first issue is almost entirely devoted to a comprehensive review of the petroleum industry in 1921 under the above headings, and, as such, is a most useful number. It is well put together, carefully printed, and the illustrations are good, and we can only express the hope

that future issues will conform to the standard aimed at by the promoters, and certainly achieved at the outset. The entire absence of an endeavour to influence the purchase of particular oil shares—an unfortunate feature of so many petroleum publications—is a sound policy which, if adhered to rigidly, will go far to establish this journal on a firm basis.

IN the Annual Report for 1921 of the Council of the Institution of Mechanical Engineers it is announced that the Thomas Hawksley Gold Medal for 1922 for the best paper published in the society's proceedings of the previous year has been awarded to Prof. E. G. Coker for a paper written in conjunction with Dr. K. C. Chakko and Mr. M. S. Ahmed on "Contact Pressures and Stresses." Other awards are grants of 20*l*. each to Mr. R. L. Smith and Mr. G. E. Sandland from the Sir Robert Hadfield prize fund for their communication entitled "An Accurate Method of determining the Hardness of Metals, with particular reference to those of a High Degree of Hardness." Prizes from this fund will not be offered again, and the unexpended balance of the capital sum will be used for assisting research. It is also announced that a scheme has been established in conjunction with the Board of Education for the award of National Certificates and Diplomas on the results of group part- and full-time courses at approved technical schools and colleges.

THE second annual report of the Industrial Fatigue Board to the Medical Research Council (pp. 65, H.M.S.O., 1922, 1*s*. 6*d*. net) is far more than a mere Report of the Board; only fourteen of its sixty-five pages are devoted thereto. The remainder consists in an instructive and valuable analysis of the published work of the Board, divided into the following five sections:—(i.) scope and method of its investigations; (ii.) hours of labour, spells, rest pauses, etc.; (iii.) other conditions of work, such as temperature, humidity, ventilation, and lighting; (iv.) methods of work, including vocational selection and guidance, and time and motion study; and (v.) miscellaneous points, *e.g.* organisation, human and technical factors in efficiency. The Secretary of the Board, Mr. D. R. Wilson, is to be congratulated most heartily on the report and on his successful organisation of its varied activities. Of these it is noteworthy that a large proportion (one half of the reports issued by the Board and of papers based on work done for it) have been contributed by investigators who have received special training in experimental psychology.

THERE has recently been issued "A List of Seismological Stations of the World" as vol. 11, No. 15, of the *Bulletin of the National Research Council* (U.S.A.). It was compiled under the auspices of the Section of Seismology of the American Geophysical Union, with the co-operation and assistance of the Research Information Service of the National Research Council. This list is incomplete owing to conditions prevailing generally after the world-war, and it is desired to correct and complete the information in the files of the Research Information Service in preparation for a revised edition of the publication. To that end a further revised *questionnaire* is being distributed with the printed list. Extra copies of the *questionnaire* are available, and will be sent to all who have additional information to contribute. It is requested that every one who notes errors or omissions in the list as issued should bring these to the notice of the Section of Seismology of the American Geophysical Union, addressing communications in care of the Research Information Service, National Research Council, 1701, Massachusetts Avenue, N.W., Washington, D.C., U.S.A. It is hoped, further, that complete as well as accurate information may be supplied concerning all stations not now fully described.

BRIEF statements on the position of the various research committees appointed by the Institution of Mechanical Engineers from time to time appear in the Report of the Council for the past year. The Committee on Alloys Research under the chairmanship of Sir John Dewrance has completed its work on aluminium alloys and is continuing that on the alloys of iron. Research work on the stresses in tools and material cut has been carried out by Prof. E. G. Coker, using polarised light and transparent models, for the Cutting Tools Research Committee, also under the chairmanship of Sir John Dewrance, and Col. Compton has experimented on the simplest form of cutting. Work for the Hardness Tests Research Committee, under the chairmanship of Dr. W. C. Unwin, has been carried out by Dr. T. E. Stanton at the National Physical Laboratory on the comparison of ball and cone tests and of scratch and indentation tests for very hard steels. The Steam-Nozzles Research Committee, under the direction of Capt. H. Riall Sankey, has investigated the efficiency of Parsons' nozzles; the expenditure of this committee during the year exceeded 900*l*., and a balance of less than 200*l*. remains. Work for the Wire Ropes Research Committee, of which Mr. C. W. James is chairman, has been carried out by Dr. W. Scoble on repeated bending tests of wire ropes.

THE representative meeting at Glasgow of the British Medical Association will begin on July 21. The statutory annual general meeting commences on July 25, and the presidential address will be delivered by the president-elect, Sir William Macewen, during the same evening. Prof. J. Graham Kerr is to give a popular lecture on the evening of July 28. The following have been elected presidents of sections: Prof. T. K. Monro, medicine; Dr. G. M. Robertson, neurology and psychological medicine; Mr. A. S. Percival, ophthalmology; Prof. R. Muir, pathology; Prof. H. A. Thomson; Mr. R. MacN. Buchanan, microbiology (including bacteriology); Prof. J. A. McWilliam, physiology; Dr. A. K. Chalmers, public health; Prof. A. Macphail, anatomy; Prof. J. Glaister, industrial diseases and forensic medicine; Mr. L. A. Rowden, radiology; and Sir Robert W. Philip, tuberculosis. The honorary local general secretary is Dr. G. A. Allen, 22 Sandyford Place, Glasgow, W.

Our Astronomical Column.

The Partial Solar Eclipse of March 28.—This eclipse is a successor, after twelve lunations, of the large eclipse of last April. On this occasion the central line has moved southwards, crossing Brazil and the Sahara. The whole of the British Isles enjoy a partial eclipse, the magnitude of which diminishes from 0·20 at Greenwich to zero at the Shetlands. At Greenwich the eclipse begins at 1.19 p.m. at the lowest point of the disc, attains its greatest phase at 2.15, and ends at 3.8. The only observations of importance that can be made are the timing of the contacts and the watch for lunar mountains at the edge of the moon.

Photography of the Ultra-violet Solar Spectrum.—MM. Charles Fabry and H. Buisson give an account of their work in this field in the *Astrophys. Journ.* (December). They state that existing material on this region is unsatisfactory; Rowland's map is disturbed by a spectrum of another order; that of Higgs stops at λ3000; and Cornu's map was made by hand from Simony's photographs. Fabry and Buisson's photographs were taken at Marseilles in May and June 1920. They used two quartz spectrographs, the prism edges in them being perpendicular to each other, and state that they thus eliminated diffuse light of longer wave-length, which is one of the chief difficulties in this region. Another difficulty, due to the rapid increase in exposure-time as the wave-length grows shorter, was overcome by using an occulting screen, which was moved by hand at a calculated rate along the spectrum during exposure; the extreme exposures were in the ratio of 1 to 1000. They state that they were able to estimate the varying amount of ozone present in the air by its absorbing effect on these short waves. They give the mean amount of ozone in the air as 0·4 c.c. per cubic metre; as this is much larger than the amount near the ground, they conjecture that it is mainly at a great height (say 50 km.). Two reproductions are given of the spectrum from λ2898 to λ3150; the definition is good and numerous lines are shown, the wave-lengths of which are promised shortly; they include the lines designated *r*ST*t*U. The region λ2965 to λ3030 appears on both photographs, the agreement being good, but with differences in the relative intensities of lines.

The authors note that the intensity of spectrum at the sun's limb is about half that at the centre, this factor remaining nearly constant throughout the region studied. They conclude that the fairly abrupt termination of the spectrum at λ2898 is due to the terrestrial, not the solar, atmosphere.

A Criticism of Majorana's Theory of Gravitation.—The *Astrophys. Journ.* for December contains a criticism of this theory by Prof. H. N. Russell. It will be remembered that the theory, which was based on the apparent alteration in the weight of a mass of lead when surrounded by mercury, asserts that gravitation is subject to absorption by intervening matter. Prof. Russell shows that a sphere composed of homogeneous spherical layers would still attract external bodies according to the inverse square law; as though its mass were concentrated at the centre; thus it would not give rise to any motion of perihelia, as some have supposed. However, the apparent mass of the sphere, as measured by its attraction on external bodies, would be less than its true mass, the deficiency increasing as the central condensation of the matter in the sphere increases. It is then proved that a massive planet would be considerably nearer to the sun than a planet of small mass with identical period. Jupiter, in particular, would be nearer to the sun by 1 per cent. than the accepted distance; but this is inadmissible, since it would produce an error of 7′ in the geocentric place when the planet was in quadrature.

Another test applied is the difference between the heights of the tides when the sun and moon respectively are above and below the horizon. It is shown that the theory would give results totally at variance with observation. Lunar theory supplies a further test, since the attraction of the sun on the moon would produce an acceleration greater by 1·6 per cent. than that experienced by the earth. Prof. Russell concludes that Majorana's theory must be abandoned; he suggests tentatively that the phenomena observed by Majorana might be explained on the assumption that the presence of a large mass itself diminishes the masses of neighbouring bodies: "the space-curvature produced by one mass of matter might be modified by the superposition of that due to another." He admits, however, that this theory also gives rise to difficulties.

The Definition of a Nova.—The Rev. J. G. Hagen directs attention to the advisability of formulating a definition of a nova which takes into account our present knowledge of the nebulous material surrounding new stars, and also class O stars and planetary nebulæ (*Astrophysical Journal*, vol. 54, No. 4, p. 229). Seeliger, so long ago as 1886, put forward the idea that temporary or new stars originated from collisions between stars and cosmic nebulæ, and this theory is now generally adopted. Dr. Hagen's view is that by assuming that the nebulæ are cometary—that is, become luminous at the approach of stars—many facts of observation are explained. Thus the observations account for nearly all the peculiarities of new stars, especially the range of magnitude, shape of the light-curve, character of the spectrum, and the rarity of occurrence; they also show a physical similarity to the O stars and planetary nebulæ.

The collision between the star and the nebula is discussed and the possible results of four types of encounters are given. Then it is shown that a transit without contact might produce a nova with a relatively small range of variation. If the star grazed the nebula and the occurrence was repeated occasionally an irregular variable would be the result. The passage of the star through the nebula might result in a nova of the ordinary type and in a star with a nebulous envelope like an O star. If the star were captured by the nebula a variable of the δ Cepheid type or a planetary nebula would be evolved. The definition of a nova is thus given: "A cometary nebula brought temporarily into close proximity or contact with a bright star."

The Stellar Magnitude of the Ringless Saturn.—Mr. J. van der Bilt investigates this subject in *Bull. Astron. Instit. of Netherlands*, No. 6. Capella, Vega, Procyon, Spica, Pollux, Regulus, and Polaris were used as comparison stars, their magnitudes being revised by the author's observations. The value obtained for Saturn in opposition (Ringless) is 0·84 mag., that given by Müller being 0·877. The chief value of this work lies in the deduced value of the planet's albedo. Similar determinations made when the rings are wide open will give a determination of their albedo, and may give a clue to the constitution of the ring-particles. Mr. van der Bilt has also investigated the effect of phase angle on magnitude, and found the change for 1° of Saturnicentric angle between sun and earth to be 0·050 magnitude, which is in good accord with the mean of other observers.

Research Items.

CLASSIFICATION OF NEMATODES.—Dr. H. H. Cobb sets forth in *Nematology* (8) a classification of nematodes "based on a study of several hundred genera" and depending chiefly on the characters of the mouth and related organs; and in the following part (9) gives systematic descriptions of about one hundred, mostly free-living, new species of nematodes, which form the type-species of nearly as many new genera. Among the morphological points may be noted the following: the large percentage of species with pointed setæ, the complex distal ends of the cephalic setæ in some species indicating their sensory nature, and the presence in a large group of nematodes of six well-developed pharyngeal onchia or spears having an outward stroke and adapted for digging.

FORESTRY IN SWEDEN.—The Forestry Research Institute (Skogsförsöksanstalt) of Sweden, with the view of making its scientific publications better known to the general public, has recently begun the free issue of a series entitled *Skogliga Rön*, which gives the main points of the larger memoirs, emphasising those of direct practical importance. No. 1, by Olof Tamm, deals with the constitution of the soil in the primæval forest of Northern Sweden. The Institute, in addition to its periodical *Skogen*, publishes leaflets, of which we have received *Flygblad* No. 23, by E. Wibeck, on some new forest-cultivating machines, such as root ploughs and sowing apparatus, and *Flygblad* No. 24, by O. Tamm, discussing the dependence of forest growth on the mineral constitution of the soil. Those interested can obtain these publications on application to the Institute at Experimentalfältet, Stockholm.

THE DOVE MARINE LABORATORY, CULLERCOATS.—The Report for the year ending June 30, 1921, of the Dove Marine Laboratory, Cullercoats, is devoted chiefly to an account of trawling investigations carried out in the inshore waters of the coast of Northumberland, which were suspended in 1913 and renewed in 1920. Prof. Meek concludes, from an examination of the rings on the otoliths of the plaice, that the spawning season of 1917, and probably also that of 1916, was a poor one, and that the fry resulting from it were subjected to unfavourable conditions. He thinks that this may perhaps be due to the flooding of the inshore waters with oil, which occurred in the war, during the pelagic period of the eggs and fry. The trawling investigations of 1920 are compared in detail, especially as regards plaice, with those carried out before the war, from 1892 to 1913, and an account is given of the results of marking experiments made with the same fish. An interesting discussion on the migrations of the plaice and other fishes in the area is added. The important feature of the remainder of the Report is Mr. Storrow's paper on herring shoals. Samples from shoals extending from Stornoway and the Shetlands in the north to Yarmouth in the south were analysed as regards age and maturity, and samples of Irish fish were treated in the same way. Attention is directed to the fact that herrings in their fourth year form the most important constituent of the summer fishery along the east coast of Britain, and the author concludes that the fluctuations in this fishery depend largely upon the success of the spawning and rearing of the season four years before that of fishing.

IRISH ESKERS.—Mr. J. de W. Hinch, in a paper on "The Eskers of Ireland" (*Irish Naturalist*, vol. xxx p. 137, 1921), criticises the recent memoir by Prof. J. W. Gregory (*Phil. Trans. Roy. Soc.*, Section B, vol. ccx.), in which it is maintained that a large part of Ireland was submerged under the sea during the formation of the boulder-clay that now occupies the plainland. Mr. Hinch points out that this revival of an old view, which was very natural in its day, ignores the work done in glacial geology in Ireland for the last thirty years. If it is necessary, as some writers think, to regard eskers as deposited in water, a lake must be postulated; but the problem of the marine shells found in abnormal positions has been successfully met without demanding a submergence, in accordance with the widening of our knowledge of the behaviour of "continental" ice-sheets.

THE POST-GLACIAL CLIMATIC OPTIMUM IN IRELAND.—Mr. J. de W. Hinch, of the Geological Survey of Ireland, has recently discussed "The Post-Glacial Climatic Optimum in Ireland" (*Irish Naturalist*, vol. xxx. p. 85, 1921). He regards the warm damp epoch when the Littorina sea prevailed in the Baltic area as representing an optimum which declined towards present-day conditions. The hazel, for instance, had then its most northern fossil boundary, and regions of high arctic vegetation became sub-arctic. The oak and the elm have now a more southerly limit than at this optimum. Mr. Hinch now shows that the marine fauna of the estuarine days, overlying submerged peat on so many parts of the Irish cost, contains a number of molluscan species that have similarly migrated southward, but which were formerly present in abundance in a more northern habitat. The improvement in climate at the epoch of the submergence which gave us the estuarine clays may thus be regarded as an optimum, or near an optimum, which has not been maintained in more recent times.

LABRADOR AND NEW QUEBEC.—Memoir 124 of the Geological Survey of Canada, by Prof. A. P. Coleman, deals concisely with the "North-eastern part of Labrador, and New Quebec," and will be useful to geographers who wish to gain an insight into a territory that embodies many late glacial features, though it lies on the latitude of the Orkneys. The landscapes in the Memoir are excellent, and among them there is an example of the most puzzling feature of solifluxion in cold tundra lands, where the polygonal areas of soil become surrounded by walls of stones coarser than the average in the soil. As the author remarks, the effect produced is "as if the finer materials, sandy or gravelly rather than muddy, ascended and spread out from the centre, crowding the coarser blocks to the edge." No stratæ intervene in N.E. Labrador between sediments that are probably Huronian and glacial deposits that are referable to an early stage of the Pleistocene ice-age. The later glaciations from the Labrador centre seem never to have reached the Atlantic coast. The raised beaches occur below the 400 ft. contour-line, and are attributed to the depression of the land by the continental ice, which here was probably only 2000 ft. in thickness. Prof. R. A. Daly's study of the post-glacial warping of the region immediately to the south, including Newfoundland, was published in the *American Journal of Science*, vol. cci. p. 381, 1921, and in it he corrects previous statements, referred to by Prof. Coleman, that raised beaches occur in Newfoundland above 500 ft. The famous

labradorite-rock of Paul Island comes within the area described by Prof. Coleman. For this, Sterry Hunt's unfortunate name anorthosite is retained; even so acute a recorder as Dr. A. Holmes has been led astray by this term, and has stated that anorthose is the French equivalent for plagioclase.

SULPHUR IN ILLINOIS COAL-BEDS.—The University of Illinois Bulletin, vol. xviii. No. 36 (Bulletin No. 125) contains the results of an investigation by Messrs. H. F. Yancey and Thomas Fraser upon the mode of occurrence of sulphur in certain of the coal-beds of Illinois. It is shown that the sulphur is present partly in the form of pyrites and partly in certain organic compounds; the former may be either macroscopic or microscopic. The technical importance of these distinctions lies in the fact that it is practically only the sulphur present in macroscopic pyrites which can be separated by washing. In some cases a certain amount of sulphur is present as sulphates, but there were only traces of these present in the coals examined. Pyritic sulphur is characterised by extreme irregularity of distribution in the coal-bed, mainly due to the concentration of the pyrites in coarse bands or lenses. On the other hand the vertical distribution of organic sulphur is comparatively uniform at given points in the same bed, though in the mine as a whole the variations may be considerable; nevertheless it is more uniformly distributed than pyritic sulphur. There is no definite relation between the occurrence of organic and pyritic sulphur. The amount of the former is quite important, the percentages in three mines being :—

	I.	II.	III.
Pyritic Sulphur . . .	47·3	47·7	60·5
Organic Sulphur . .	52·7	52·3	39·5

In 104 face samples taken in the three beds, organic sulphur exceeded pyritic sulphur in 49 samples.

EVAPORATION FROM LARGE EXPANSES OF WATER.—This subject is dealt with in the *Meteorological Magazine* for January and February. In the January issue reference is made to Dr. H. Jeffreys, who submitted the problem to mathematical analysis in 1918, and who adopted the simple hypothesis that the rate of evaporation depended only on difference of vapour pressure. It is mentioned that Mr. M. A. Giblett in *Proc. Roy. Soc.* A, vol. 99, 1921, makes a further advance by allowing for the strength of the wind. Valuable information is given as to the total amount of evaporation under various circumstances. It is asserted that the same amount of air picks up less moisture if it crosses the ocean quickly than if it goes slowly; the more vigorous evaporation does not make up for the shorter time of passage. The February *Meteorological Magazine* deals with "The Evaporation from the Sea," by G. Wüst (Institut für Meereskunde, Berlin, Oct. 1920). This publication was taken for discussion at the Meteorological Office at the evening lecture on February 6 last. An estimate is given of the zonal distribution of evaporation, which is said to be most rapid between the latitudes 10° and 20° north and south. Comparison between the estimates of evaporation and the rainfall over the ocean indicates that evaporation exceeds precipitation between latitudes 40° N. and 40° S., except in the cloudy equatorial belt, whilst outside these limits precipitation is in excess of evaporation.

METEOROLOGY IN MEDICINE.—At a meeting of the Royal Meteorological Society in the University, Edinburgh, on September 7 last, a paper on Meteorology in Medicine, with especial reference to the occurrence of malaria in Scotland, was read by Dr. Angus G. Macdonald. The paper is printed in the Quarterly Journal of the Royal Meteorological Society for January. Meteorology is described as a science, and medicine as a consummate art—the practical exploitation of the data of all the sciences for the conservation of mankind. Referring to the re-appearance of malaria indigenous in England in the years 1917, 1918, and 1919, temperature results are given for the months of June–September in each year. It is mentioned that it would appear to be safe to infer that any month having a mean temperature of 60° F. may suffice to produce malaria in England, given other conditions favourable. The conditions in the years mentioned were associated with the presence of a large mass of infection imported in soldiery from the East. The recent period of malaria is contrasted with the last previous recorded outbreak of malaria in England in the years 1856–59, when a period of abnormally high temperature is shown to have occurred. This period also coincided with the return of infected soldiery from Eastern Europe, this time from the Crimean War. An abnormally cold year followed in 1860 which brought the infection to an end. In relation to the maturation of the infection especial reference is made to the mosquito associated with high temperatures. These general considerations are applied to occurrences of malaria in Scotland, and much valuable information is given.

INDUSTRIAL LIGHTING.—In a paper read before the Illuminating Engineering Society on February 28, Mr. L. Gaster discussed "Ideal Requirements in Industrial Lighting and Practical Solutions." Ideal lighting conditions should enable work to proceed by night as safely and efficiently as by the best daylight. Practical possibilities were illustrated in the recommendations of the Home Office Departmental Committee on lighting in factories and workshops and the codes of industrial lighting adopted in various American states. The latter, while more detailed and elaborate, were based on the same general principles, namely, sufficient illumination, avoidance of glare, and elimination of inconvenient shadows. Mr. Gaster laid stress on the fact that sufficient illumination was only part of the problem. A distinction must be drawn between recommendations and legislative measures. Any form of code must be so framed as to prevent abuse of industrial lighting and yet impose no hardship on manufacturers. The Home Office in this country had proceeded wisely step by step, adopting the principle of "government by consent." Their first report, besides recommending general statutory provision requiring adequate lighting, proposed certain values of illumination, easily obtained, in the interests of safety and general convenience. Their second interim report proposed a simple rule for avoidance of glare, which could be met in various ways. In future it was intended to study values of illumination and conditions of lighting necessary for efficient work in various industrial processes, co-operation being invited from representatives of the industries concerned. This process might take some time, but would ensure decisions being taken on a sound and scientific basis. In conclusion Mr. Gaster mentioned that industrial illumination was becoming a subject for international treatment. It was being considered by an international committee appointed at the recent technical session of the International Illumination Commission, and it was also receiving attention from the International Labour Office operating under the League of Nations at Geneva.

Carbon Monoxide in Gas.

By PROF. JOHN W. COBB.

THE following paragraph appeared in *The Times* for February 11, under the heading "Carbon Monoxide Peril."

"The Board of Trade has drafted a special Order under the Gas Regulation Act, 1920, relating to carbon monoxide in gas used for domestic purposes. The Order provides that: No gas undertakers as defined by the Gas Regulation Act, 1920, shall supply any gas for domestic purposes containing carbon monoxide unless such gas possesses the distinctive pungent smell of coal gas. The Order requires the approval of both Houses of Parliament."

The announcement needs some explanation, as probably nobody in this country has ever come across a public gas supply without a very distinctive and pungent smell.

When Sir George Beilby and the Fuel Research Board were called upon by the Board of Trade, some time ago, to make recommendations for the future regulation of public gas supply, they recognised in effect that radical improvements and economies by the gas manufacturers could be secured by the gasification of the fixed carbon of the coal by some such process as that of the steaming of vertical gas retorts or the gasification of coke in external generators with steam—the so-called water-gas process.

The increase in the carbon monoxide content of the gas so involved depended upon the extent to which the fixed carbon was gasified. The recommendations then made form the basis of the Gas Regulation Act of 1920, but when the Act was passed it was decided that the Board of Trade should institute inquiries on two special points, one of which was "whether it is necessary or desirable to prescribe any limitations of the proportion of carbon monoxide which may be supplied for the gas used for domestic purposes." The inquiry was made and evidence taken by a Committee from witnesses who regarded this matter from different points of view, and set out their arguments at length. It became plain that the economic advantages offered by the new Act depended very largely on freedom to supply gas containing more carbon monoxide, and that even on the side of hygiene the position was not so simple as might appear at first sight. Any danger from carbon monoxide had to be placed against the improvement of public health which would result from the progressive abolition of smoke as gas replaced raw coal for heating purposes, and it had to be realised that in no circumstances would it be practicable to supply gas containing little or no carbon monoxide, since ordinary "straight" coal-gas might contain 10 per cent or more.

It is not surprising, therefore, that the Committee recommended against statutory limitation of carbon monoxide in public gas supply. It was, however, possible that the conditions of manufacture might at some time or place be changed to such an extent that the gas then supplied to the public would be nearly odourless unless some means were taken to confer a smell upon it, and to meet that possibility of the future it was recommended that the distribution of an odourless gas should be made an offence.

The Board of Trade Order, which has just been drafted, will carry that recommendation into effect. It is no doubt hoped that it will also have on the public mind the beneficial effect of a psychological antitoxin, which seems to be needed at the present time.

During the last two months of severe weather, the number of accidents from gas poisoning undoubtedly increased. Various factors have been operative in bringing this about, including the tendency to restrict ventilation owing to the cold, and to use gas heating appliances of all kinds, in all sorts of places, and particularly in bedrooms. Public attention, however, having been directed to the fact that carbon monoxide in public gas supply might increase considerably in the future owing to the Gas Regulation Act, people have arrived at the mistaken conclusion that such increase had already taken place and was solely responsible for these accidents. It would, as a matter of fact, greatly surprise the present writer to learn that the carbon monoxide content of gas responsible for any one of these accidents was above the permissible limit recommended by the advocates of restriction before the special Committee to which reference has been made above. In the gas supply of Leeds, which has come under the writer's own tests, the percentage of carbon monoxide has been actually considerably lower than it was during the summer months of the coal strike, and no higher than in the preceding winter. Nor is there any reason to suppose that the condition so described is exceptional.

The Brain of Rhodesian Man.

AT a meeting of the Royal Anthropological Institute held on February 14, Dr. W. H. R. Rivers, president, in the chair, Prof. G. Elliot Smith described the brain of Rhodesian man.

The excellent endocranial cast which Mr. Frank Barlow, of the Natural History Museum, has been able to obtain from the Rhodesian skull is of exceptional importance. In the first place, it affords evidence which settles once for all the position of *Homo rhodesiensis* in the human family and its varying degrees of affinity to the different members of the family; and, secondly, it provides very precise information concerning the size, shape, and stage of development of the brain of Rhodesian man, so that when the endocranial casts of Pithecanthropus, Eoanthropus, and *Homo Neanderthalensis* are compared with it and the whole series is considered in the light of the new information, a fuller understanding of the process of evolution of the human brain is attained. Moreover, the endocranial cast enables us definitely to settle the dispute as to the posture of Rhodesian man, or at any rate as to how he carried his head.

Prof. John Hunter, of the University of Sydney, has made a series of exact orthogonal projections of the endocranial casts of the extinct types of the human family and of the anthropoid apes, and has shown that Rhodesian man's head was thrust forward on his tremendously massive neck at an angle almost exactly intermediate between that of the gorilla and modern man—a degree of obliquity almost identical with that of Gibraltar man and probably a little more than that of the man of La Chapelle-aux-Saints. The peculiarly distinctive features of the base of the skull of Rhodesian man corroborate this interpretation. The cranial capacity is 1280 c.c., which is roughly equal to that of the Gibraltar skull, but much smaller than all the other members of the

Neanderthal species. It is definitely bigger than the Piltdown cast.

Like the endocranial casts of Pithecanthropus and Eoanthropus, that of the newly discovered skull reveals a marked deficiency in the prefrontal and inferior temporal areas. But as in all these primitive members of the human family, there is an obtrusive prominence in the auditory territory which suggests that the cultivation of the acoustic symbolism necessary for the acquisition of articulate speech was a very important, if not the dominant, factor in the attainment of the human status. This localised expansion in the superior temporal area is responsible for the peculiar form of all primitive human brains, *i.e.* their relatively great width and flatness. The expansion of the cortex has been carried a stage further than in the Piltdown brain and has led to a fuller development of the inferior parietal territory, but the superior parietal area is still ill-developed and flat.

Thus the Rhodesian cast reveals a stage definitely more primitive than that of Neanderthal man and helps us to understand the features of the latter. The significance of the peculiarities, so far as they shed light upon the evolution of the human brain, was discussed, and the speaker expressed his gratitude to Dr. Smith Woodward of the British Museum for affording him the opportunity for studying the Rhodesian skull and the endocranial cast obtained from it.

The president, in opening the discussion, said that he had been particularly struck by the demonstration of the development of those parts of the brain that are connected with mind, and it was interesting to note that those parts which were latest in development of the child were those in which Rhodesian man stood intermediate between the gorilla and modern man.

Dr. Smith Woodward regretted the absence of geological or palæontological data which might throw light upon the age of the skull. Any attempt to determine its age must depend upon the character of the skull itself. Prof. Elliot Smith had made a beginning of the scientific study of this evidence, and it should be possible to determine its position in the human series apart from geological evidence. Prof. W. Wright said that Prof. Elliot Smith had given a clear demonstration of the development of the brain from the lowest primates to Dean Swift. Would it not be possible to go a little further and prophesy that the future development of the brain would be in the direction of filling those parts of the cranial cavity which were at present ill-filled? He agreed that the author was justified in now placing Pithecanthropus definitely within the human family. Prof. Parsons said that the present communication indicated the value of the endocranial cast in ethnological investigation, and that this method of study should be applied to the investigation of the problems connected with modern races.

Evolutionary Faith and Modern Doubts.

In a notable address on the above subject at the Toronto meeting of the American Association for the Advancement of Science, which is printed in *Science* for January 20, Dr. William Bateson discusses particularly the changes in point of view which have followed each other since the Darwinian period and the end of last century. The morphological school worked itself out, and was followed by the development of genetic experiments. It was seen that the gradual transformation of species over large areas was an unacceptable doctrine. From field studies of pairs of species it was concluded that both could not have come from an intermediate ancestor through gradual divergence by natural selection, nor could either have given rise to the other by such a process.

Then Mendelism seemed to furnish an explanation of the discontinuity of species—a discontinuity which had long been denied by those evolutionary philosophers who were not systematists. Nevertheless, the result has been disappointing, and the attempt to explain evolution in Mendelian terms has finally been dropped. This is because evolutionary conceptions have dealt with zygotes, or the bodies of plants and animals as we see them, while genetic research has revealed the interactions of an inner world of gametes upon which the zygotes depend for their origin. Dr. Bateson further records his full conversion to the belief that the chromosomes are directly associated with the characters of the zygote. "The transferable characters borne by the gametes have been successfully referred to the visible details of nuclear configuration."

Although we see variations in abundance on all hands, the origin of species is still obscure, and genetic analysis has not enabled us to account for certain phenomena, especially the origin of new dominant characters and of sterility. The question of species-origin is believed to be concerned with the base upon which transferable characters are implanted, but of this base we at present know nothing. Dr. Bateson concludes a remarkable survey with an appeal for closer co-operation between geneticists and systematists, and finally points out that the fact of evolution is not in doubt, although the manner of the origin of species remains a mystery.

R. R. G.

The Teeth of the Nation.[1]

The lecturer began by directing attention to a series of skulls exhibited, kindly lent for the occasion by Sir Arthur Keith. Skulls of Neolithic date showed perfect dentition, though the teeth were worn a good deal by attrition; the skulls of to-day exemplified the ravages of dental caries, or of the equally prevalent disease of gums and jaws called pyorrhœa. One modern skull with a perfect set of teeth was the rarest specimen he could show. Caries was not unknown in past ages, and even the teeth in the Rhodesian skull exhibit it. The seriousness of the increase in dental decay in recent times is such that the Ministry of Health has appointed a special Committee to investigate its causes and prevention. Cleanliness is a necessary duty, and the tooth-brush, unless supplemented by antiseptic mouth-washes, is an imperfect instrument. The danger is the accumulation of food-débris in chinks and crevices and the formation of acids such as lactic acid by bacteria, especially if the food is soft and sticky and contains easily fermentable sugars of the glucose type. Such acid has a solvent action on the protective layer of enamel, and in time on the dentine which it covers.

The teeth, however, are not mere ornaments to be

[1] Abstract of a discourse delivered at the Royal Institution in February 10 by Prof. W. D. Halliburton, F.R.S.

kept clean locally. They are living structures, and their power of resistance varies with the general health, and this, like the health of the teeth, mainly depends on a supply of natural foods in proper quantity, especially in early life when tooth-formation occurs. Early life means especially embryonic life, and the proper feeding of expectant mothers is a *sine qua non*. Sophisticated and patent foods are specially harmful, for they, as a rule, lack the necessary "vitamins," which were then described in outline. Bad teeth in their turn undermine the general health, and, by forming foci of infection, lead to general ill-health, indigestion, blood-poisoning, rheumatoid affections, and the like, and so a vicious circle is produced, the abolition of which becomes a national duty.

After a general account of what is called "calcium metabolism," a series of lantern-slides was shown to illustrate not only the structure of the various parts of a tooth, but also the stages in their development, in which the cells responsible for the elaboration of the enamel prisms and the layers of dentine with its tubules and the nerves, etc., within them were seen. Occasion was taken to press home again the possibilities of injury and the necessity for care, especially in early stages and in early life, the word "early" including fœtal life. In conclusion, the lecturer looked forward to a time in the not far distant future when the teeth of the nation might be its pride, and not a source of lamentation and pain.

The Brown Bast Disease of the Para Rubber-tree.[1]

By DR. S. E. CHANDLER.

DURING the early years of rubber planting in the East considerable optimism prevailed in certain quarters as to the powers of the Para rubber-tree (*Hevea brasiliensis*) to resist disease in its new home. The planting of such great areas with a single crop plant, however, was practically certain to result sooner or later in fungal disease, to say nothing of insect attack; and, although little was (and still is) known as to the functions of latex in plants, it was safe to predict that the regular withdrawal of considerable quantities of latex from the trees would result in physiological disturbances which might become a factor of commercial importance. Events have proved these views to be well founded. As compared with many crops, rubber has been comparatively free from visitations, but several fungal diseases are now recognised and insect pests are not unknown; while a disease hitherto ascribed to physiological causes, and known as "brown bast," has attained such importance as to constitute the most dangerous cultural menace to the rubber-planting industry at the present day.

Brown bast is a disease of the bark[2] of tapped trees, but it does not involve the death of the tree, or even of the affected bark. The disease may be recognised by a difficulty in obtaining latex on tapping to the usual depth, followed ultimately by the cessation of latex flow (when the tree is said to be "dry"), and is further characterised by a brownish or olive-green discoloration of the middle and inner bark, which may show a definite brown line on the tapping cut near the cambium. External signs of the disease may be lacking, but in the more severe cases the outer bark often scales and splits longitudinally and an exudation of latex occurs. This condition sometimes results from the secondary development of woody "burrs," nodules, or plates within the diseased tissue, and, unless the case is dealt with, these bodies may cause the bark ultimately to become so knotted and irregular as to be useless for tapping purposes. The formation of burrs and nodules, however, is not necessarily associated with brown bast, as has been shown by Bateson, Bryce, and others.

Brown bast was widely reported as an epidemic in the plantations during 1916–18, and a satisfactory method of treatment became a matter of prime importance. Pending exact knowledge as to the cause of the disease, the methods recommended were based on the observations that affected latex-vessels do not again function, that the diseased portion of the bark is useless for further tapping, and that the disease "spreads" in the bark. Planters were therefore advised to remove the diseased tissue, either by "scraping" the brown bast tissue from the bark, or by carefully "stripping" off the bark down to the cambium. In the latter case, especially, measures should be taken to protect the delicate exposed surface so that a satisfactory regeneration of the bark by the cambium may take place. The removal of the superficial layers of the affected bark, followed by the application of warm tar to the exposed surface, has also been practised.

It was early recognised, however, that the best chance of devising adequate measures of control would result from a correct understanding of the nature of the disease, and considerable research on this subject has been carried out by British and Dutch botanists in the East. So far, attempts to associate the disease definitely with bacterial or fungal attack have failed, and at the present time brown bast cannot be ascribed to any causal organism, though it has been claimed by Keuchenius that bacteria are present in the diseased tissue. With the bulk of evidence against a parasitic origin of the disease, most investigators have fallen back on the theory that brown bast is a physiological disease, the result of metabolic disturbances as to the nature of which, however, little or no information is available.

Recently a series of important publications on the etiology of brown bast have appeared almost simultaneously. The results obtained are of exceptional interest, inasmuch as the work has been carried out by investigators widely separated and working independently on material derived from several different planting countries. Rands (1) and (2) has dealt with the disease in Java and Sumatra; Sanderson and Sutcliffe (3) in British Malaya; Gandrup (4) in Java; while Farmer and Horne (5) and (6), in London, have examined diseased material from British North Borneo and Malaya. These in-

[2] The term "bark" is here used in the planter's sense of the tissue actually involved in the tapping operation.

vestigations throw much light on the anatomy of the diseased tissue and the probable immediate cause of brown bast, while in the case last mentioned it seems probable that a valuable advance has been made towards a correct understanding of the nature of the disease.

The two papers of Rands (1) and (2), who published preliminary reports in 1919 and 1920, are complementary. The first-mentioned paper contains a full statement to date of the results of the author's investigations commenced in 1918 at the instance of the Director of the Government Rubber Estates in the Dutch East Indies, and still in progress. Rands's results support the view of the non-parasitic origin of the disease, and indicate that the repeated withdrawal of the latex from the same tissues is the chief causal factor concerned. The drained tissues respond by secreting a gum, which in its effects prevents a further loss of latex. The time-interval between successive tappings and the system of tapping adopted appear to be the most important predisposing factors; in the author's experience a heavy occurrence of the disease is invariably associated with a drastic system of tapping. The second paper records the botanical (anatomical) evidence on which the results are based. According to Rands, brown bast appears to be a special type of wound-gum secretion favoured by conditions which promote the vital activity of the tree. The characteristic brown discoloration of the diseased bark is stated to be due to the deposition of a yellow plastic "gum" in the cavities of the latex-vessels and in many of the intercellular spaces of the bark (phloem) parenchyma, thus recalling similar observations made by Bobilioff.

The gum is formed, not by the breaking down of cell-walls, but as a secretion of the protoplasts of the parenchymatous cells adjacent to the latex-vessels. It passes into the latter through the common cell-wall (which is thereby stained yellow), and also into the existing intercellular spaces or into such spaces formed and enlarged under the stimulus of the secretion. It is secreted in largest quantities during the wet season, and is most abundant in vigorous trees in full growth. Investigation showed that the gum is practically identical with the "wound-gum" formed locally as a result of artificial wounds made in the wood and bark of the tree, and is similar to the corresponding product in other plants. It differs from the true gums, however, in its chemical reactions. The clogging of the latex-vessels appears to be the chief factor in arresting the latex flow, but the coagulation of the latex within the vessels is also indicated as a contributory factor. Under the highest powers the gum is seen to possess a well-marked alveolar structure which is not an artefact. Rands was unable to determine whether the gum-formation results from enzyme action, as has been suggested in the case of the gummosis of Prunus. As regards the burrs, Rands's results in general confirm the previous work of Rutgers, Bateson, Bryce, and others, and especially the suggestion of Bateson that burr-formation is favoured by excessive tapping. The woody burrs arise from the activity of a secondary cambium formed about a group of gummed latex-vessels; the varied form of the mature structure (pea-shaped, knobby, or plate-like) depends upon the disposition and extent of the secondary cambium.

The book by Sanderson and Sutcliffe (3) is primarily intended as a practical guide for estate managers in diagnosing the disease and in treating affected trees. The authors lay special emphasis upon the desirability of early treatment, and recommend "stripping" of the bark, not only as curative in effect, but also as the simplest and cheapest procedure. A considerable portion of the book, however, is devoted to the results of a microscopical study of the disease, and the authors claim their work to be the first attempt to describe the pathological anatomy of brown bast and to formulate a theory by which the observed facts may be explained. They regard brown bast as physiological in origin, and consider tapping to be its prime cause. As regards pathological anatomy, Sanderson and Sutcliffe find that the constant and characteristic feature is a meristematic activity of the parenchyma cells of the bark. Other characters described by them, viz. the deposition of "tannins" and crystals of calcium oxalate, the occurrence of abnormal numbers of stone-cells at unusual depths in the bark, the depletion of starch, and the presence of globules of "oil or fatty matter" (suggested possibly as a substitution product for starch, or as the result of a breaking down of that substance), are regarded as secondary symptoms arising from the meristematic activity.

Elsewhere, however, the authors state that the occurrence of "tannins" is not characteristic of the disease, while large numbers of oily globules are not constantly present. The meristematic tissue originates at a point roughly corresponding to the depth of tapping, and occurs almost invariably in the immediate vicinity of the latex-vessels. The result is a partial displacement of these vessels, which, in consequence, are often ruptured, the latex percolating into the intercellular spaces, where it coagulates. The latex within the vessels also appears to be coagulated *in situ* (*cf.* Rands), possibly through the agency of the by-products of the metabolism of the actively dividing cells. The coagulated latex is considered to be an additional source of irritation, stimulating the surrounding tissue to further meristematic activity.

The views put forward by these authors as to the immediate origin of the disease are interesting. They consider that the abnormal meristem may be due to the stimulus arising from the wound meristem formed just beneath the surface of the tapping cut, or it may be a secondary effect of the abnormal vigour of the cork cambium which early arises over the previously tapped surface to form the renewal bark. Sanderson and Sutcliffe regard it as "highly probable" that the growth of this cork cambium "provides the stimulus for starting meristematic activity at an equal, or almost equal, depth in the cortex below the tapping cut, *i.e.* in the untapped portion of the cortex below." Such induced cambial activity spreading from the renewal bark was first described by Lock, but it is not quite clear from the present paper whether Sanderson and Sutcliffe have independent evidence of a similar phenomenon in the case of brown bast.

As regards burr-formation, the case is put that, while the meristem of brown bast may remain as such, it may also give rise to woody tissue internally and unlignified elements externally. It is in this latter manner that burrs originate, and the degree and character of the burr-formation depend upon the amount and disposition of the meristem concerned. Sanderson and Sutcliffe ascribe considerable importance to the production of stone-cell tissue as a secondary character of brown bast. In this respect they are supported by other writers. The cells on the outer limits of the meristem may be largely converted into stone-cells, which sometimes form extensive scleritic masses resulting in the scaling of the outer bark. The observations of Gandrup (4) are interesting in this connection, since this worker shows that in the young Hevea plant the stone-cells arise among the thickened prosenchymatous pericycle fibres (bast fibres), which later are almost completely replaced by a ring of stone-cells.

The papers of Farmer and Horne (5) and (6) give the results of a research carried out in the botanical laboratories of the Imperial College of Science and

Technology on material received from British North Borneo and Malaya. The work formed the subject of an exhibit at the Rubber Exhibition of 1921, and was briefly noticed in NATURE of June 16 last, p. 499. It is understood that further work is in progress, and that a full illustrated account of the results will be published. These authors have concentrated attention upon the earliest stages of the disease, and obtained results which definitely advance the problem a step towards solution. In transverse sections of diseased bark, numerous minute golden-yellow spots of irregular outline were observed in the phloem from the cambium outwards. Under high magnification these coloured areas sometimes appeared to resemble intercellular spaces (*cf.* Rands's work), but on careful examination the golden areas were found to be sections of necrotic *sieve-tubes*, the waved outlines in many cases being clearly transverse sections of the large vertical sieve-plates characteristic of Hevea phloem. In the young phloem the disease is confined to the sieve-tubes, but in the older tissue phloem parenchyma, medullary-ray cells and latex-vessels have been involved in the local tissue degeneration. Commonly, a diseased area was found to be more or less completely surrounded by an active meristem (" wound-cambium "), which in some cases gave rise to lignified elements and constituted the initial stages of a burr.

It will be seen that this investigation emphasises the fact that, quite apart from the latex-vessels, elements (sieve-tubes) of vital importance in the nutritional processes of the plant are injured during tapping. The sieve-tubes cease to function and, in becoming disorganised, initiate the condition known as brown bast. The disease, therefore, is primarily due to phloem necrosis analogous to the cases of similar disease reported in the potato and in Liberian coffee. Observations were also made regarding the origin of burr development. It is stated that, as a result of the activities of the wound cambiums, diseased groups of cells become enclosed in " pockets " of stone-cells. Sanderson and Sutcliffe also refer to stone-cells derived from the pathological meristem in the bark tissue.

In reading this series of papers for the first time it is difficult to believe that the authors are dealing with the same problem. No evidence for a parasitic origin of the disease is brought forward in any case, but their respective investigations lead the authors to differ in their views as to the immediate origin of the disease. Sanderson and Sutcliffe point to an induced meristematic activity in the bark as the characteristic feature of the pathological anatomy. To Rands the disease is a special case of gummosis which is the outcome of a wound response resulting from tapping; while Farmer and Horne regard phloem necrosis as, " beyond doubt," the immediate cause of the disease. The present writer carefully examined Horne's remarkable preparations and camera-lucida drawings shown at the Rubber Exhibition last year, and recently he has been allowed to compare further the drawings with the illustrations accompanying the papers of Rands and of Sanderson and Sutcliffe. He considers that the true relations of the seemingly conflicting results are apparent on the view that a difficult piece of anatomy has been carried out to varying degrees of finality by the respective workers. In the case of Horne's work there is little doubt that his investigation has shown that the immediate cause of brown bast is a degeneration of the sieve-tubes and neighbouring elements, accompanied by the more or less complete localisation of the necrotic area by an active meristem. Rands's research appears to have fallen just short of complete success. In spite of his histological methods to prove his " intercellulars " to be such, comparison of his drawings with those of Horne strongly suggests that they are the necrotic sieve-tube areas illustrated by the latter worker. It is remarkable that throughout Rands's anatomical paper he uses the word " sieve-tube " twice only, though in the only diagram in which sieve-tubes appear each of the two sieve-tubes figured is blocked with " gum." Rands's view that the disease is a type of " gummosis " is by no means beside the mark; it may well be so regarded in its ultimate symptoms, but he failed to detect the primary cause. The abundant meristematic activity emphasised by Sanderson and Sutcliffe would appear to be a secondary character, and is possibly a development of the pathological meristem referred to by Farmer and Horne. It may be significant in this connection that the bark examined by Sanderson and Sutcliffe was from trees which " had been taken out of tapping for some little time owing to brown bast," and in which, therefore, there may have been time for the meristem to reach considerable development. The suggestion that the pathological meristem is formed as a result of the stimulus afforded by the activity of the cork-cambium of the tapped bark above the diseased area is interesting, and the authors might usefully have given further evidence in support of the contention.

There would appear to be some difference of opinion as to the condition of the starch reserves in the diseased bark. Sanderson and Sutcliffe report that starch is usually absent, or present in small quantities only, and regard this depletion as accounted for by the demands for food materials made upon the neighbouring tissue by the meristematic cells. Rands, however, states that evidence based on observations of the starch reserves indicates that the response of the tissues, resulting in the " disease," is more the effect of a stimulus connected with a loss of latex than of an actual depletion of (starch) reserve food, though he suggests the possibility of effects caused by the temporary depletion of other food substances, *e.g.* the proteid constituents of the latex which are known to suffer a reduction as the consequence of hard tapping.

If the initial occurrence of phloem necrosis is confirmed, there will remain the problem of the cause of this condition. The solution of the problem is inseparably connected with the general question of phloem necrosis in plants. Thus light may be thrown on brown bast by the recent work of Quanjer, who claims that phloem necrosis in the potato can be transmitted from one plant to another.

As pointed out by Farmer and Horne, the current investigation of brown bast disease points clearly to the urgent need for a wider understanding of the general physiology of Hevea, in which, of course, the laticiferous system would call for special attention. The present writer ventures to suggest that before this question (of which little is as yet known) can be dealt with successfully, it is essential that fuller knowledge of the anatomy and histology of laticiferous tissue in general should be available. Useful pioneer work has been done by Meunier, but the papers under review show how far from complete such knowledge is at present in the case of Hevea alone. There is little doubt that, as in zoology, *comparative* anatomy would be highly suggestive and helpful. The study should extend at least to carefully selected arboreal laticiferous plants, of which the various " rubber-trees " which have been cultivated or exploited commercially would probably be sufficient, since the character of their laticiferous systems varies greatly in important features. The essential

difference between the laticiferous systems of Hevea and Funtumia, and the presence in Castilloa, Funtumia, and Landolphia of a striking development of laticiferous tissue in the xylem (medullary rays), connecting the latex-tubes in the phloem radially with those in the pith, are but instances of a significant state of affairs. A thorough study of this question could not fail to lead to important scientific knowledge which, in competent hands, might well result in practical applications. Again, such striking facts as the occurrence in *Funtumia elastica* of an excellent latex rich in caoutchouc, while in the closely related *F. latifolia* (often found growing with the former species) there is a commercially useless latex containing abundant "resins" in place of caoutchouc, present problems, difficult indeed, that might well receive more attention at the hands of biological chemists. The preliminary anatomical work would be best carried out in the tropics, but with a little organisation much might be accomplished in this country, as is evident from the fact that observations which may prove to be the key to the correct understanding of a baffling disease of Hevea have recently been made in London.

Dairy Cattle and Milk Production.

THE urgency of the problem of milk supply has of late years caused much attention to be devoted to the improvement of dairy cattle, and to the increase of milk supply on an economic basis. During the last twenty-five years the Danish Milk Recording Societies (*Journ. Min. Agric.*, October and November 1921) have been working towards the improvement of herds by the gradual elimination of unproductive cows, and Government grants have been made to aid them in the formation of strains of dairy cattle producing a higher yield of butter. The keeping of private and official handbooks is encouraged, and a special feature is made of two-year competitions between entire herds, the best herds being awarded prizes and officially recognised as breeding centres. The earlier work dealt entirely with the yield of cows, but later it was realised that the character of the bull was of equal importance with regard to milk production, as high milk-yielding capacity is a character that can be inherited through the sire as well as the dam. By close observation of records and careful breeding, attempts have been made to obtain bulls with a good influence on the milk yield, with considerable success. As Denmark is chiefly a butter-producing country, the main object of the milk-recording societies has been to raise the percentage of butter fat, thus aiming at improvement of quality more than at increase of quantity.

The milk problem is by no means confined to European countries, but various aspects of dairying are being investigated elsewhere, as in the Madras Agricultural College, India (Bull. No. 79). Special consideration is given to business aspects as well as to the technical methods of dairying. Approved methods of selection are applied to the dairy herd, unprofitable cows being weeded out, and pedigree registers are maintained. A creamery is also run for the preparation of butter on a commercial scale, milk being purchased from outside to supplement the home supply. The prospects of success are good, and a future seems to be before the dairy industry of India if it is managed with scientific and business knowledge.

One point which has a close bearing on dairy-farming is the varying cost of milk production, which has ranged from 3½*d.* to 4*s.* 7½*d.* per gallon since 1908 on Yorkshire farms for which records are available (*Scottish Journ. Agric.*, vol. 4, No. 4). Some of the factors concerned are not under the control of the producer, and are due to increase in the labour and food bills, and to the increased depreciation of the cows. In pre-war time the cost of attention per cow per week varied from 1*s.* 6*d.* to 2*s.*, but owing to the rise in agricultural wages it is now 4*s.* 6*d.* to 6*s.*, an increase which is estimated to have added 4*d.* per gallon to the pre-war cost of milk production. The cost of food has risen on every hand. Grazing is far more expensive owing to increased cost of manure and upkeep, home-grown food costs at least twice as much to produce, and, above all, purchased food has risen so much in price that it is probably the one factor more than any other which has been responsible for the high prices of milk during recent years. During the war, too, the difference in value between in-milk and dry cows greatly increased, and this depreciation in value has had its effect upon the cost of milk production. The tables drawn up indicate that in some cases the total costs have exceeded pre-war costs by 300 per cent., but happily there are indications that the inflated prices are easing off, and they show signs of being still lower in the near future.

W. E. B.

University and Educational Intelligence.

CAMBRIDGE.—The Smith's prizes have been awarded to E. A. Milne, Trinity College, for an essay on "Studies in the Theory of Radiative Equilibrium," and to G. C. Steward, Gonville and Caius College, for an essay on "The Aberration-Diffraction Problem." A Rayleigh Prize has been awarded to T. A. Brown, Trinity College, for an essay "On a Class of Factorial Series."

J. A. Carroll, Sidney Sussex College, has been elected to an Isaac Newton Studentship, and the Studentship of W. M. H. Greaves, St. John's College, has been renewed for a year.

Regulations have been proposed for the degrees of M.Litt. and M.Sc. The chief difference from the Ph.D. regulations are that a student must for these degrees do research for two years as against three for the Ph.D. The Board of Research Studies publishes its second annual report. There have now been 143 research students admitted, of whom 5 have already taken the degree of Ph.D. Of these 95 are working in scientific subjects—physics with 22, chemistry with 16, and botany with 12, head the list.

LONDON.—The under-mentioned French professors in the Faculty of Medicine of the University of Paris will lecture (in French) at the Rooms of the Royal Society of Medicine, 1 Wimpole Street, W.1, at 5 P.M., on the dates stated:—

March 20, Prof. H. Roger (Dean of the Faculty), "Les fonctions du Poumon"; March 23, Prof. A. Chauffard, "Syndrome Humoral de la Goutte"; March 27, Prof. P. Duval, "Données actuelles de la Chirurgie Intra-Thoracique."

PROF. H. R. DEAN has been appointed as from June 1 next to the University Chair of Bacteriology tenable at University College Hospital Medical School. Since 1915 Prof. Dean has been Professor of Pathology and Pathological Anatomy in the University of Manchester. He has been Horace Dobell Lecturer for the Royal College of Physicians, and is the author of numerous papers on pathological and bacteriological subjects.

Calendar of Industrial Pioneers.

March 16, 1864. Richard Roberts died.—A man of invention, whose genius did not save him from ultimate poverty, Roberts was the son of a Welsh shoemaker. He worked at various trades in different parts of England, and in 1816 settled in Manchester, where he made improvements in engineers' machine tools, such as planing machines, and in textile machinery. His self-acting mule was patented in 1825.

March 16, 1908. William Petrie died.—Sent at the age of nineteen to study at Frankfort-on-Main, Petrie devoted himself to electricity and magnetism, and in 1847 invented one of the first self-regulating arc lamps, which in the following year was displayed from the portico of the National Gallery. His efforts proving financially unsuccessful Petrie turned his attention to the management and equipment of chemical works.

March 17, 1806. David Dale died.—A notable Scotch industrialist, Dale began life as a Paisley weaver. He gained a fortune, however, as an importer of yarn, and in 1783, by the establishment of spinning mills at New Lanark, founded the cotton industry of Lanarkshire.

March 17, 1887. William Denny died.—The son of Peter Denny, one of the founders of the Dumbarton firm of shipbuilders and marine engineers, William Denny was one of the most scientific naval architects of his day, and at his Leven shipyard constructed the first privately-owned experimental tank, over which he placed an inscription to Froude, "The greatest of experimenters and investigators of hydrodynamics."

March 18, 1899. Sir Douglas Strutt Galton died.—A captain in the Royal Engineers, Galton did valuable work in connection with the application of iron to railways, structures, and the laying of the Atlantic cable, and was well known for his writings on sanitary science. He held various public offices, was made an honorary member of the Institution of Civil Engineers, and in 1895 served as president of the British Association.

March 19, 1888. Thomas Russell Crampton died.—An assistant to Gooch in the Great Western Railway, Crampton in 1848 set up in business for himself, and in that year constructed the locomotive "Liverpool," one of the most powerful engines of the time. It embodied many special features and was adopted as the type of locomotive for some of the French railways. Crampton also laid the first practical submarine cable from Dover to Calais, and with Fox carried out the Berlin water-works.

March 21, 1888. Ludwig August Colding died.—From the Polytechnic School at Copenhagen Colding passed into the public service and became an inspector of roads. While thus engaged, in 1843 he wrote his "Theses concerning Moving Forces," a paper which entitles him to a place among the founders of thermodynamics. He published other scientific memoirs and rose to be chief engineer of Copenhagen.

March 21, 1914. August Wöhler died.—One of the earliest and most distinguished of Prussian railway engineers and a pioneer in the testing of materials, Wöhler began his investigations on railway axles in 1852, and in 1859 established at Berlin an experimental station for the testing of iron and steel under repeated stresses.

March 22, 1831. William Symington died.—The maker of the first practical marine steam engines, Symington by his work for Patrick Miller in 1788 and for the Earl of Dundas in 1801 solved the problem of driving boats by steam, but failing to obtain support for his projects he sank into poverty and died in London a disappointed man. He is buried in St. Botolph's, Aldgate.

E. C. S.

Societies and Academies.

LONDON.

Geological Society, February 17.—Mr. R. D. Oldham, president, in the chair.—R. D. **Oldham**: The cause and character of earthquakes (Anniversary Address). The term "earthquake" is here applied only to a disturbance which can be felt, and as such, it is a form of elastic wave-motion of extreme complexity; this may be distinguished as the orchesis of the earthquake. In addition there is, in some cases, a molar, permanent displacement of the solid rock, which forms the mochleusis, which is probably the secondary result of a more deep-seated disturbance, which has been distinguished as the bathyseism. The origin of the elastic wave-motion must be a sudden disturbance not more than ten miles down, and in this outer portion of the earth's crust the only sudden disturbance conceivable is fracture. In certain cases such fracture, accompanied or not by displacement, has been recognised at the surface, and measurements of the displacements show that a state of strain must have existed before actual rupture took place, but give no indication of the rate of growth of the strain. This problem can only be attacked through the variation in the frequency of earthquakes, and only one existing record, the Italian one, is available. From this the rate of growth of strain is, at slowest, such that the breaking-point will, on the average, be reached in a year at most, and, at the quickest, may be of such rapidity as to be analogous to a separate explosion for each earthquake. Changes producing such strains are probably to be referred to the material below the crust. Researches on the change of bulk resulting from a change in the mineral aggregation of the same material indicates one means by which the effect may be brought about. The cause of the great majority of earthquakes is a rapid growth of strain, due to changes in the material underlying the outer crust of solid rock.

February 22.—Prof. A. C. Seward, president, in the chair.—C. W. **Andrews**: Description of a new Plesiosaur from the Weald Clay of Berwick (Sussex). The parts preserved are the posterior region of the skull, numerous cervical and dorsal vertebræ, the shoulder girdle, and the humeri. The bones lay mixed up, in an intensely hard matrix. The skull is very imperfect: it resembles the skull of *Plesiosaurus capensis*, Andrews, from the Uitenhage Series of South Africa. The cervical vertebræ are also very similar to those of the African species, having the central portion of the articular surfaces deeply cupped; they have also inter-vertebral discs, possibly of calcified cartilage, between successive centra. The clavicular arch in the shoulder girdle is large and well developed, being very similar to that of some Lower Liassic forms. The retention of this primitive condition in this and other Wealden Plesiosaurs may be the consequence of their comparatively sheltered life in a fluviatile or estuarine habitat. The name *Leptocleidus superstes* is suggested for the specimen.—T. **Landell-Mills**, A. Smith **Woodward**, and A. **Gilligan**: The Carboniferous rocks of the Deer-Lake district of Newfoundland. The Carboniferous rocks form a synclinal flexure with its longer axis trending north-east and south-west. Underlying these is a limestone series of undetermined age resting on highly-folded gneisses and schists of Archæan age. A thick mantle of Pleistocene deposits covers the whole region, but deeply-trenched valleys give good exposures of the Carboniferous rocks. Fishes and plant-remains occur abundantly at several horizons in the Lower Carboniferous shales, but no fossils have been found in the Upper

Carboniferous. The mineralogical constituents of the deposits are remarkably like those making up rocks of similar age in the north of England, hence it is inferred that the deposits on both sides of the Atlantic were derived from the same land-mass. The fish-remains are fragmentary; they represent three species closely related to those found in the Lower Carboniferous of Scotland. A group of ribs with the caudal fin and scattered scales belongs to a Dipnoan fish; a new species of Uronemus and some specimens of a Palæoniscid fish are also found.

Zoological Society, February 21.—Prof. E. W. MacBride, vice-president, in the chair.—Miss L. E. **Cheesman**: (1) The position and function of the siphon of the amphibious mollusc, *Ampullaria vermiformis*. (2) The habits, in captivity, of the fresh-water crab, *Cardisoma armatum*.—H. **Blegvad**: Animal communities in the southern North Sea.—C. Tate **Regan**: The Cichlid fishes of Lake Victoria.—C. F. **Sonntag**: (1) On the vagus and sympathetic nerves of the Edentata. (2) On the vagus and sympathetic nerves of *Hyrax capensis*.

Physical Society, February 24.—Dr. A. Russell, president, in the chair.—H. **Levy**: The number of radio-active transformations as determined by analysis of the observations. The expression for the nth product of a series of radio-active transformations is represented as the sum of n terms of the type $a_n e^{-\lambda nt}$. When n is known, the coefficients a_n and λ_n can be determined. A criterion for determining n, the number of transformations, by successive evaluation of a system of determinants constructed from the observations is given. The value of n is found from the order of the particular member of the system that vanishes.—C. H. **Lees**: A graphical method of treating Fresnel's formulæ for reflection in transparent media. The directions of the reflected and refracted rays having been determined by known graphical methods, a construction, based on Fresnel's formulæ, is given for finding the amplitudes of the electric vectors of these rays, in and normal to the plane of incidence.

Aristotelian Society, March 6.—Prof. J. S. Mackenzie in the chair.—S. N. **Dasgupta**: The Logic of the Vedanta. The earliest Upanisads, forming the concluding part of the Vedic literature, were completed certainly before 500 B.C. The main doctrine found in them is that self is the ultimate reality. This self is not the Ego but pure consciousness, which was regarded as supremely unchangeable. The early Buddhist philosophy sought to prove that everything was changing and that there was nothing which could be regarded as permanent. The nihilistic school of Buddhism as interpreted by Nagarjuna and Aryadeva (A.D. 100) demonstrated, by critical and dialectical reasoning of the type which Mr. Bradley has used, that our ordinary conceptions of experience were absolutely relative and were therefore indefinite and indefinable. The idealistic Buddhists accepted this position and held that all worldly experience is due to mental construction. The Vedanta, as explained by Sankara, and as interpreted by Sriharsa and Madhusudana Sarasvati and others, held that pure consciousness, as revealed in immediate experience and as distinct from its particular form and content, was self-contained and absolutely real. Particular forms are relative and mutually interdependent. They are definable either as being or as non-being for they participate in the nature of both. They are the modifications of a separate logical category called the indefinite and have the same sort of logical status as illusions. They appear as existent by virtue of their relation with pure consciousness which is absolutely unchangeable and self-contained and immediate. Everything which has any form or content is thus a joint manifestation of the absolutely real, *i.e.* the consciousness, and the category of the indefinite. The nature of all that is relative is that it has being in some sense and it has no being in another, and it cannot therefore be regarded either as positive or negative. This necessitates the acceptance of the indefinite as a separate logical category which explains the logical status of all that is relative.

Paris.

Academy of Sciences, February 20.—M. Emile Bertin in the chair.—E. **Borel**: Functions of a real variable capable of differentiation without limit.—H. **Douvillé**: The Nummulitic to the south of the Pyrenees.—G. **Gouy**: The tensions and pressures of Maxwell in magnets and dielectrics. Maxwell has given two expressions involving the field (H) and the induction (B), one for magnets and a second for dielectrics. Only the first of these, a tension of $\left(\frac{1}{4\pi}\right)$BH along the lines of force and a pressure p in all directions of $\left(\frac{1}{8\pi}H^2\right)$, appears to give exact results in all cases.—G. **Julia**: Functional equations and conformable representation.—J. **Rémoundos**: The coincidence of lines and the plane elastic curve.—R. **Lagrange**: Some applications of the absolute differential calculus.—B. **Gambier**: Point correspondence between two surfaces with exchange of conjugated into orthogonal systems and *vice versa*.—M. **Frontard**: Cycloids of sliding of soils.—J. **Petitpas**: The work expended in the mechanical working of wood.—P. **Bourgoin**: The velocity of combustion of colloidal powders.—A. de La Baume **Pluvinel**: A *coudée* telescope designed for the application of the method of equal heights.—M. **Baudouin**: The prehistoric material representation of the Pleiades with ten stars in a rock basin in Epesses (Vendée). This prehistoric engraving on a stone basin is unique in that ten instead of the usual seven stars are represented.—G. **Perrier**: The differences of altitude of the stations of the meridian arc of the Equator. Fifty-four of the stations on this arc, now being measured, are at heights between 3500 and 4500 metres, whilst towards the south the triangles fall suddenly to the sea-level. The reduction of the observations is discussed and it is shown that a term commonly neglected in geodesic operations must in these reductions be taken into account.—MM. **Courtines** and **Villey**: Barovariometers with capillary flow. The apparatus consists of a glass bulb, thermally isolated by a vacuum, communicating with the outside air by a capillary tube and furnished with a sensitive manometer indicating variations in the external pressure. The conditions under which the instrument can be made to furnish accurate figures are worked out.—Mlle. P. **Collet**: Thin layers formed by mixtures of glycerides.—H. **Chaumat**: The measurement of power in alternating currents in some abnormal cases.—M. **Galibourg**: The utilisation of the thermo-electric force of contact for the identification of certain steels. Diagrams of the apparatus used are given and some figures obtained for carbon, silicon, nickel, and chrome tungsten steels. Taken in conjunction with the Brinell test, the determination of the thermo-electromotive force at 120° C., under the conditions indicated, suffices to determine the nature of the steel without an analysis.—M. **Curie**: The action of the red and infra-red rays on phosphorescent sulphides. The author puts forward the hypothesis that the action of the extinguishing rays consists in making the medium

conduct by detachment of electrons from the atoms of sulphur.—G. **Mouret**: The prolongation of the fracture of Argentat (Corrèze) in the region of Dorat (Upper Vienne and Vienne).—L. **Dussault**: The Tam Dao and the region of the lower river Claire (Tonkin).—C. **Gorceix**: The formation of the "Gouf de Cap-Breton." A close study of the profile of this cavity shows that it cannot be regarded as an estuary or valley. The best explanation of the observed facts appears to be the assumption of a band of gypsum-salt formation; the gypsum and the salt have been dissolved by water and the associated clay washed out.—J. **Fromaget**: The geology of the environs of A Mi Tchéoü (Eastern Yunnan).—M. **Gignoux**: The presence of the Tortonian at Valence (Spain).—E. **Wertheimer**: The entero-hepatic circulation of the bile acids. A description of an experiment confirming the views of Stadelmann on the passage of glycocholic acid in bile of the dog. The elimination of the bile acids takes place exclusively through the intermediary of the portal vein.—F. **Maignon**: Researches on the physiological and therapeutic properties of the diastases of the tissues. The existence of synthesising diastases. An account of experiments on the injection and ingestion of diastases extracted from various organs (thyroid, suprarenal capsules, ovary, pancreas, etc.). The action of these diastases is specific, in the sense that those extracted from the liver exert hepatic functions only, those from the thyroid affect the thyroid secretion, etc. These diastases have no action when administered to healthy subjects whose organs are working normally.—R. **Jeannel**: The geographical dispersion of *Silphidae Catopinae* during the Tertiary period.—R. **Noël**: The phenomena of condensation of fatty bodies on the surface of mitachondria.—R. **Argaud**: Some functions of the tumoral megacaryocyte and especially its vasoformative function.—A. **Goris** and A. **Liot**: New observations on the culture of the pyocyanic bacillus on definite artificial media. The amides could not be used for the culture of this bacillus; amino acids could be used, but growth did not take place so readily as with ammoniacal salts of dibasic acids.—L. **Cavel**: The method of purification by means of activated sludge and its application to the separative system.—J. **Glover**: Electrical auscultation of respiration at the commencement of tuberculosis. A new method of auscultation based on the use of amplifying microtelephonic stethoscopes.—E. **Sergent** and A. **Donatien**: The stomox as a propagator of trypanosomiasis in dromedaries.

Official Publications Received.

Bulletin of the National Research Council, vol. 3, Part I., No. 16, December: Research Laboratories in Industrial Establishments of the United States. By Alfred D. Flinn. Revised and enlarged by Ruth Cobb. Pp. 135. (Washington: National Academy of Sciences.) 2 dollars.

Smithsonian Institution: United States National Museum. Bulletin 113: Life Histories of North American Gulls and Terns: Order Longipennes. By Arthur C. Bent. Pp. x+345+93 plates. Bulletin 114: A Revision of the King Snakes: Genus Lampropeltis. By Frank N. Blanchard. Pp. vi+260. (Washington: Government Printing Office.)

Pp. iv+charts 2-67. (Paris: Ministère de l'Agriculture.)

Diary of Societies.

FRIDAY, MARCH 17.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.

INSTITUTE OF TRANSPORT (at Royal Society of Arts), at 5.—F. Pick: The Operation of an Omnibus Company, with reference to Capacity and Cost under Given Conditions.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—P. C. Dewhurst: British and American Locomotive Design and Practice.

INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 7.—C. C. H. Wade: The Electron Theory.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—G. H. Ayres: Power Factor Improvement.

ROYAL SOCIETY OF MEDICINE (Electro-therapeutics Section), at 8.30.—Dr. M. Legge and others: Discussion on the Pathological Changes produced in Subjects rendered Unconscious by Electric Shock, and the Treatment.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. A. P. Laurie: The Pigments and Mediums of the Old Masters.

SATURDAY, MARCH 18.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radioactivity (3).

PHYSIOLOGICAL SOCIETY (at University College).

MONDAY, MARCH 20.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section), at 7.—Capt. H. Whittaker: Hydro-electric Course at the University of Grenoble.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. D. Searles-Wood: The Building Timbers of the Empire.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—Prof. R. F. A. Hoernlé: Some Byways of the Theory of Knowledge.

ROYAL SOCIETY OF ARTS, at 8.—L. G. Radcliffe: The Constituents of Essential Oils (Cantor Lectures) (1).

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—H. Temperley: The Geography of the Treaty of Rapallo.

TUESDAY, MARCH 21.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Arthur Keith: Anthropological Problems of the British Empire. Series I. Racial Problems in Asia and Australasia (5).

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Feiling: The Interpretation of Symptoms in Disease of the Central Nervous System (Goulstonian Lectures) (1).

ROYAL STATISTICAL SOCIETY, at 5.15.—J. Y. Hart: Sickness Data of Public Elementary School Teachers in London 1904–1919.
MINERALOGICAL SOCIETY (at Geological Society), at 5.30.—Sir William Bragg: Recent X-ray work on the Crystal Structure of Organic Substances.
ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—G. Blaine: Notes on the Zebras and some Antelopes of Angola.—R. I. Pocock: The External Characters of some Histricomorph Rodents.—H. R. Hogg: Some Spiders from South Annam.
INSTITUTION OF CIVIL ENGINEERS, at 6.—W. Willox: All-Electric Automatic Power Signalling on the Metropolitan Railway.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—S. Bridgen: Landscape from the Practical Side.
RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.—Sir Oliver Lodge: Magnetism—and the Ether (Fifth Silvanus Thompson Memorial Lecture).

WEDNESDAY, MARCH 22.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Sir Charles J. Holmes Lionardo da Vinci as a Geologist.
ROYAL SOCIETY OF ARTS, at 8.—Prof. A. P. Laurie: The late Mr. Holman Hunt's Experiments on the Permanency of Artists' Oil Colours.

THURSDAY, MARCH 23.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. P. Chalmers Mitchell: The Cinema as a Zoological Method (2).
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Sir Richard Glazebrook: The Specific Heats of Air, Steam, and Carbon Dioxide.—Lord Rayleigh: A Photographic Spectrum of the Aurora of May 13-15, 1921, and Laboratory Studies in connection with it.—F. A. Freeth: The System: $Na_2-CO_2-NaCl-H_2O$.—M. A. Catalán: Series and other Regularities in the Spectrum of Manganese.—D. W. Dye: Calculation of a Primary Standard of Mutual Inductance of the Campbell Type and Comparison of it with the similar N.P.L. Standard.—P. E. Shaw and N. Davy: The Effect of Temperature on Gravitative Attraction.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Feiling: The Interpretation of Symptoms in Disease of the Central Nervous System (2).
CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—F. Whelen: The League at Work (League of Nations Union).
CONCRETE INSTITUTE, at 7.30.—S. F. Staples: Floating Docks.

FRIDAY, MARCH 24.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Prof. H. E. Armstrong: The Indigo Situation in India.
PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.
INSTITUTION OF PRODUCTION ENGINEERS (at Institution of Mechanical Engineers), at 7.30.—E. Fairbrother: Inspection Methods.
JUNIOR INSTITUTION OF ENGINEERS, at 8.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. F. G. Donnan: Auxiliary International Languages.

SATURDAY, MARCH 25.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radioactivity (4).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, MARCH 17.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (9).
KING'S COLLEGE, at 5.—Prof. R. Robinson: Orientation and Conjugation in Organic Chemistry from the Standpoint of the Theories of Partial Valency and of Latent Polarity of Atoms (3).
TAVISTOCK CLINIC FOR FUNCTIONAL NERVE CASES (at Mary Ward Settlement, Tavistock Place, W.C.1), at 5.30.—Dr. H. C. Miller: The New Psychology and its Bearing on Education (8).
BIRKBECK COLLEGE, at 8.—F. Hodges: Trade Unionism. (Meeting arranged by the London Branch of the National Union of Scientific Workers.)

SATURDAY, MARCH 18.

THE POLYTECHNIC (Regent Street, W.1), at 10.30 A.M.—P. A. Best: The Romance of Commerce.
HORNIMAN MUSEUM (Forest Hill), at 3.30.—H. N. Milligan: The Natural History of Elephants.

MONDAY, MARCH 20.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. H. Roger: Les fonctions du Poumon.

TUESDAY, MARCH 21.

KING'S COLLEGE, at 5.30.—F. H. Rolt: Accurate Measurements in Mechanical Engineering: The Use and Testing of Gauges (5).
UNIVERSITY COLLEGE, at 5.30.—Col. W. M. St. G. Kirke: Imperial Defence as affected by the War (2).

WEDNESDAY, MARCH 22.

SCHOOL OF ORIENTAL STUDIES, at 12.—Miss Alice Werner: Bantu Mythology and Folklore (5).
EAST LONDON COLLEGE, at 4.—Prof. F. E. Fritsch: Certain Aspects of Freshwater Algal Biology (6).
SCHOOL OF ORIENTAL STUDIES, at 5.—M. de Z. Wickremasinghe: Tea and Rubber Industries in Ceylon.
KING'S COLLEGE, at 5.15.—Prof. N. Bohr: The Quantum Theory of Radiation and the Constitution of the Atom (3).
HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (9).
UNIVERSITY COLLEGE, at 8.—The Current Work of the Biometric and Eugenics Laboratories (6). Dr. M. Greenwood: Occupational Mortality.

THURSDAY, MARCH 23.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. A. Chauffard: Syndrome Humoral de la Goutte.
SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. L. D. Barnett: The Hindu Culture of India (4).
KING'S COLLEGE, at 5.30.—Dr. O. Faber: Reinforced Concrete (10).
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. E. Stilgoe: Water (1): Its Storage and Filtration (Chadwick Lecture).

FRIDAY, MARCH 24.

METEOROLOGICAL OFFICE, (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (10).
KING'S COLLEGE, at 5.30.—Dr. G. Cook: Some Recent Advances in our Knowledge of the Strength of Materials.

SATURDAY, MARCH 25.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. E. Marion Delf: Science and the Food we eat.

The Universities and Colonial Scientific Services.[1]

THE unfortunate shortage of trained men at the end of the war, at a time when many of the Colonies were especially anxious for expert help in reorganisation and further development, led to various suggestions for the increase in the supply. Lord Milner, as Colonial Secretary, accordingly appointed a Committee in 1920 to investigate how the universities could best help in training men for the scientific services abroad and in securing the research necessary for the protection of the inhabitants of the Colonies against disease and for the development of their veterinary, agricultural, and mineral resources. The Committee consisted of Lord Chalmers as chairman, Sir Henry Birchenough, Sir John Rose Bradford, Sir Walter M. Fletcher, Prof. E. B. Poulton, Sir David Prain, Sir H. J. Read, Sir Stewart Stockman, and Sir Aubrey Strahan. The Committee has now issued its Report. It concludes that the universities can help mainly in two ways—in the fuller training of students and in the building up of a corps of advanced workers who would be available for the solution of especially complex problems.

The Committee's conclusion that the universities must impart to the students who desire to enter the Colonial services more than "book knowledge" will be universally approved, but the suggestion that some universities still give scientific courses without laboratory and practical instruction will be read with surprise. The Committee further insists that the men required must have "a training in the methods of research, and this involves post-graduate study." It concludes, therefore, that the universities can assist most usefully and directly by encouraging post-graduate study, and for this purpose urges that an increase of research fellowships and studentships would be of primary importance.

The Report implies that appointments in the scientific departments of the Colonies should be restricted to men who have been through post-graduate courses, but this limitation would be attended by serious drawbacks, especially in tropical colonies. The men would begin their service later and would retire when older or with a smaller pension, and the men who have taken the extra years of post-graduate work would be lower in seniority than those who had joined the service at the end of the ordinary university course. The better-trained men would thereby be debarred, as a rule, from securing the head appointments, with probably much consequent jealousy and friction. The attempt to correct this evil by dividing the staff of a small department into two grades and restricting the upper grade to men who have had post-graduate training would lead to even greater difficulties.

The Committee's conclusion implies that the courses for university degrees do not include training in the methods of research, although that training is the essential of university education. Research training should be improved, not by lengthening the time at the university, but by earlier specialisation in the case of students requiring a professional scientific qualification. The universities provide for two sets of students, whose requirements are different. They have to teach the pedagogic methods and general principles, by knowledge of which teachers may widen the mental outlook of their pupils and inculcate habits of scientific thought. They must also teach students who intend to adopt science as a profession, other than in secondary education and medicine, how to use the methods by which the various sciences have achieved their present position and may be further advanced. Now that a four years' course for the honours B.Sc. is becoming the rule, the university science courses should provide training in the methods of research for at least two of the four years for students who require it; and men so trained should be able to give useful service in the ordinary research work required in most colonial departments. The desired increase in the output of men trained for research would be even better secured by encouraging the universities to provide further teaching in research methods in the course for the B.Sc. without adopting the principle that such training "involves post-graduate study."

The second problem which the Report considers is the provision of experts to solve the specially intricate problems that would be met with from time to time. The university staffs might be expected to help in such

[1] Report of a Committee on Research in the Colonies. (Cmd. 1472.) 12 pp. 8vo. (His Majesty's Stationery Office, 1921.) 2*d*.

work, men being seconded for service as required. The Committee, however, expects such problems to be so numerous that the universities could give adequate help only if their scientific staffs were greatly enlarged. To secure this increase the Report adopts Lord Milner's suggestion that research departments should be established at those universities to which the subject would appeal by local interests or environment. Lord Milner has promised that if the universities would endeavour to collect funds from local industries for such departments, the Colonial Office would support the appeals by testifying that the establishment of new chairs and the enlargement of the professorial staffs in the departments of science throughout the universities would be a great and permanent service to the Empire.

Sir Walter Fletcher, in a reservation appended to the Report, regrets that its proposals regarding appeals for such endowments are so indefinite. He remarks that it leaves untouched the practical questions as to "Who will make the appeal? What appeal? By what mechanism or in what modes? And on what occasions?" He says that no steady cultivation of university resources for the ends proposed can be effected without a general scientific staff, and recommends a special advisory committee in each of the departments of science concerned. Sir Herbert Read replies to this criticism, in a covering letter annexed to the Report, that the Colonial Office has already the help of adequate advisory committees, and that in some subjects there are, indeed, too many. Thus, dealing with tropical medicine there are the Tropical Diseases Bureau, the Tropical Diseases Research Fund Committee, the Advising Medical and Sanitary Committee for Tropical Africa, and the Schools of Tropical Medicine in London and Liverpool. Sir Herbert Read remarks that in this case the machinery should be simplified and not enlarged; but, despite this experience, the establishment of scattered research institutes is the system which the Committee recommends. Laboratories for special researches attached to university departments are subject to the risk of lack of continuity between the work of one professor and that of his successor. This drawback may be reduced by the establishment and endowment of research chairs to superintend such laboratories; but, even if the funds could be obtained, such chairs might soon outlive their usefulness owing to changed industrial conditions.

The establishment of these independent research institutes might prove an extravagant method of conducting much of the ordinary research necessary for colonial development. A central institution, which could call on the university staffs to help with special problems, might be a far more economical method of organising this work. There is already such an institution—the Imperial Institute. The Report does not mention it, though reference is made to its work, for a letter by Lord Milner which is printed with the Report, illustrates the great economic value of scientific investigation by the discovery of the Udi coalfields in Nigeria, which was due to a survey organised by the Imperial Institute under a man whom it enlisted. The Imperial Institute is under the management of the Colonial Office, and its extensive laboratories, staff, and resources should be available for the investigation of problems connected with economic biology, geology, and mineralogy, in any part of the Empire which has not adequate scientific departments of its own. As the Committee was appointed to consider the relations of the universities to research, the Imperial Institute may have seemed outside its province. Its scheme is, however, attended by the danger of overlap of the kind which, as Sir Herbert Read remarks, has already developed not only between different independent departments, but also between all the proposed research institutes and the Imperial Institute, which was founded expressly to investigate the economic resources of the British Empire overseas.

A Monograph on Wheat.

The Wheat Plant: A Monograph. By Prof. J. Percival. Pp. x+463. (London: Duckworth and Co., 1921.) 63*s*. net.

PROF. PERCIVAL'S monograph fills one of the many great gaps in English agricultural literature by providing, for the first time in our language, a comprehensive account of the wheat plant, the most important of the cereal crops. Some idea of the magnitude of the work involved in the production of this book is derived from a statement in the preface that it is based on the study of what is "probably the most representative collection in existence," since it "includes all the races of wheats, numbering nearly 2000 forms derived from almost all wheat-growing regions of the world," whilst a brief glance at any section of the book is sufficient to convince the reader, especially perhaps the reader familiar with the crop, that this study has been peculiarly exhaustive.

Part 1 is devoted to the results of investigations on the morphology, anatomy, development, and growth of the wheat plant. When the importance of the crop is taken into consideration the existing literature on these subjects is singularly scanty, and the detailed accounts, covering some 140 pages, will save trouble to many future investigators. Further information on the cytology of the chief races of wheat and on the

details of fertilisation is still required; but, apart from this, we now possess sufficient knowledge of the minute structure and of the development of the wheat plant for most purposes.

The greater portion of Part 2 consists of a series of chapters dealing with the classification of the numerous "forms," many of which the author has had under observation for as many as twenty years. At the outset two wild species, *Triticum aegilopoides*, Bal., and *T. dicoccoides*, Körn., are recognised, together with eleven "races" or cultivated species. Eight of the latter, the small Spelt, Emmer, Macaroni, Polish, Rivet wheat, Bread wheat, Club wheat, and large Spelt, are well-known races; whilst three, *T. orientale*, Khorasan wheat, *T. pyramidale*, Egyptian cone wheat, and *T. sphaerococcum*, Indian dwarf wheat, are new creations. The first of these consists of a couple of Emmer-like varieties, differing only in awn-colour, which are characterised by the possession of long glumes and grain. The second consists of a group of five Egyptian wheats coming close to the Rivet wheats in most of their characteristics, and in leaf colour, shortness of straw, and ear shape strongly reminiscent of segregates from crosses between *T. turgidum* and *T. vulgare*. The third is an equally small group of round-grained forms coming near *T. compactum*. The further sub-division of these races into "varieties" follows the well-known system in Körnicke and Werner's "Handbuch des Getreidesbau."

But this system is not slavishly adhered to, and here and there noteworthy departures are made from it. For instance, several forms placed by Körnicke in *T. durum* are rightly transferred to the Emmer group, *T. dicoccum*. Persian Black, too—a form which has puzzled more than one systematist—is also placed in this group, to the satisfaction of those interested in the genetics of this important mildew-resisting wheat.

In the smaller groups the sub-division of the varieties into forms is a comparatively simple matter, but difficulties occur in the large races, such as *T. vulgare*. If, by way of example, one takes the first of the beardless varieties of the bread wheats, *T. v. albidum*, one finds detailed descriptions, under either a name or a number, of a dozen forms from various parts of the world, supplemented by excellently reproduced photographs of the more distinct types. But the forms themselves are capable of further sub-division. Under the description of Wilhelmina, for instance, is the statement: "Similar to this is Willem I. from Holland, Victor, Stand Up, Essex hybrid. . . ." Some of these are almost unquestionably synonymous, whilst some are distinct wheats, and a classification failing to differentiate these will disappoint many who grow wheat.

But, whatever the needs of the wheat-grower for a still finer differentiation of forms, one feels that the day for these elaborate descriptions is passing and that it is unlikely that many attempts will be made in the future to bring together and catalogue the world's numerous wheats. Even now, when the subject of wheat-breeding is in its childhood, the geneticist foresees the possibility of an accession of new forms which would reduce Prof. Percival's collection to the dimensions of a dwarf. Such a feature as the winged glume figure in Plate 179 is known to him only in one form. But it is inherited as a unit character, and though scores of forms with similar glumes are in existence at the Plant-Breeding Institute at Cambridge, many more could easily be raised. Much the same is true of that still rarer feature, the purple colour of the grain, seen in *T. d. arraseita*, which has in the hands of the hybridist given rise to a series of purple-grained Macaroni and Polish wheats, in addition to other forms of Emmers. To cope with such a "flora," the systematist of the future will probably have recourse to brief formulæ expressing the genetic constitution of each form—a system which would have many of the merits of that used in the classification of bacteria.

The systematic portion of the monograph is followed by a chapter of considerable interest on the origin and relationship of the races of wheat. Evidence from various sources—archæological, ecological, pathological, genetical, etc.—is skilfully marshalled to show their probable lines of development. The story is too long to discuss within the limits of a review, but Prof. Percival's conclusions on the origin of the bread wheats (*T. vulgare*) are too interesting to pass over. At present, as is well known, no wild species even suggestive of this group has been found. A study of the morphology of the wild and cultivated wheats has led the author to the conclusion that "there is not nor has there ever been a prototype of the bread wheats." And further: "The characters of *T. vulgare* and its allies appear . . . to be those of a vast hybrid race, initiated long ago by the crossing of wheats of the Emmer series with species of Ægilops." It so happens that many crosses have been made between the reputed Ægilops parents, *Æ. ovata* and *Æ. cylindrica*, and forms from practically all the races of wheats; but such crosses yield, at the most, sterile hybrids. The significance of this fact is recognised, but disposed of by the assumption that natural hybrids between the wild Ægilops and the Emmer prototype are more fertile under their native climatic conditions than in Central or Western Europe.

A chapter on yield follows a useful summary of most of the more important literature dealing with the hybridisation and improvement of wheat. In this

the effects of soil, cultivation and manuring, seed rate, variety, time and methods of sowing, and size of grain are considered.

One can but regret that it is not followed by a chapter on quality, in which the effects of these factors on the milling and baking properties of the bread wheats is brought under review. Such a chapter would be peculiarly welcome to both wheat-breeders and millers, even if it did no more than summarise the scattered literature on the subject. It would, moreover, go some way to justify the statement on the wrapper of the book that it is "essential to . . . plant-breeders and millers." Prof. Percival will lay workers on both these subjects under a still greater obligation if such an addition is made when a new edition of this useful volume is called for. R. H. B.

The Subjectivity of Psychology.

The Psychology of Everyday Life. By Dr. James Drever. Pp. ix+164. (London: Methuen and Co., Ltd., 1921.) 6*s.* net.

THE present generation is witnessing a sustained and persistent effort to raise psychology to the status of a science. Hitherto it has been a part of philosophy, and it is felt by psychologists that success depends wholly on their being able to detach it. There is something curiously instructive in the fact that the task is avowedly difficult. It is curious because the data of psychology are more immediate than any other data of science, and for that reason alone we should expect them to be the most easily known and the most susceptible to treatment. But the instructive thing is that this very intimacy of our relationship with the data militates against scientific treatment. All the trouble in regard to the matter arises from the fact that the objects of a science of psychology are more difficult to abstract from the subject of experience, more difficult to reify or set up with an independent status of their own, than are the objects of any recognised science, mathematical, physical, or biological.

This is obvious at once if we compare psychology with its nearest neighbour in the hierarchy, physiology. We have no trouble in presenting the functions of anatomical organs, and the processes of secretion, circulation, innervation, and the like, as objective. They are capable of mechanistic interpretation in complete detachment from anything which depends on the experience of the subject, although we are ready to acknowledge that without such experience the apparent purpose of the mechanism would be wanting. But when we try in the same way to present instincts, impulses, emotions, feelings, memory, wishes, trains of reasoning, we seem to be in a peculiar difficulty, for it is impossible to avoid not merely subjectivity, but a certain vexatious personal and individual subjectivity. Yet there is no obvious reason for this, and the more we reflect the more we are driven to recognise that while we know as matter of fact that it is so, we do not know and are unable to imagine the reason why it should be so.

The difficulty goes back at least to Berkeley. It is quite easy to imagine perfect cubes and circles and other geometrical figures existing entirely independently of the mind which knows them and to found a science on the assumption that they may or do so exist. The same is true in some measure of all the physical and biological sciences. But a wish, a pain, a thought, absolutely refuse to be detached, and will not let us imagine an abstract existence for them independently of the subject. Now Berkeley's contention was that every object of knowledge is in the same case, and therefore the physical sciences have no advantage over psychology. This, however, gives no satisfaction to the modern psychologist, for whatever be the truth of Berkeley's doctrine he knows that physics and biology possess at least a *practical* advantage which is lacking to psychology.

The little manual by Dr. Drever, which is the occasion of this reflection, is an excellent classification and general survey of the nature of the entities with which the modern science of psychology is attempting to deal. What seems to qualify the author for his task is his thorough knowledge of the older and philosophical treatment of the subject, in particular with its treatment in books like Descartes's "Les Passions de l'Ame" and Malebranche's "Recherche de la Vérité." Dr. Drever is in thorough sympathy with the scientific end, and is working towards it, yet with full consciousness and complete understanding of its origin in philosophy.

H. WILDON CARR.

The Study of Earthquakes.

A Manual of Seismology. By Dr. Charles Davison. (Cambridge Geological Series.) Pp. xii + 256. (Cambridge: At the University Press, 1921.) 21*s.* net.

TIME was when the meaning of seismology was clear and unmistakable; it was the study of earthquakes, and by earthquakes was meant the disturbance which could be felt, and, when severe, caused alarm and damage. It was known that there was a central area where the earthquake was most severe, fringed by zones of decreasing violence, until a region was reached where it was insensible to the unaided senses, though still recognisable by suitable

instruments, and when, towards the end of last century, it was found that, at distances far away from the region affected by the sensible shock, disturbances which were clearly connected with great earthquakes could be detected by suitable instruments, it was natural to suppose that the origin was the same for both. Only of recent years has it been recognised that the earthquake proper, caused directly by fracturing of the surface rocks, is but a secondary effect of a more deep-seated disturbance, or bathyseism, which, and not the earthquake proper, is presumably the origin of the disturbance represented in the preliminary tremors of the distant record.

Meanwhile, seismology has developed on two distinct lines, and in reality into two distinct sciences, differing in method, means, and requirements. On one hand, we have the newer seismology of the long-distance record, in which personal observation counts for nothing; some mechanical ingenuity is required for the design of efficient instruments, some care in the maintenance of them and their records, but after that, the discussion and interpretation are purely a matter of the higher mathematics. On the other hand, we have the older seismology, in which there is still much work to be done, even with no further mathematical equipment than an intelligent schoolboy may carry away from a modern public school, but in which the collection of data is entirely dependent on personal observation, and the coincidence of occasion and a competent observer.

With such a difference of scope and methods, it is scarcely possible for one individual to become a master of both branches, and this is illustrated by the existence of two recent text-books, both nominally of seismology; first we have the "Modern Seismology" of the late Dr. G. W. Walker, which appeared some years ago and is an admirable introduction to the newer development of the subject, but scarcely refers, and only incidentally, to the earthquake proper; then we have this book, by Dr. C. Davison, which is called a manual of seismology and devotes only a part of one chapter to the subject of Dr. Walker's book. The difference accounts for, and is indicated by, the fact that one appeared as a Monograph on Physics, the other as part of the Cambridge Geological Series.

The object, as well as the scope, of Dr. Davison's work accounts sufficiently for the fact that he devotes only part of a chapter to the newer seismology, and the treatment is adequate, in so far as it gives that amount of information which a student of the older seismology cannot afford to ignore. As a manual of that older seismology the book fills a much-felt want, for we had no satisfactory introduction to the study of the earthquake proper. Well arranged and clearly expressed, the only adverse criticism which can be made is that the ground is possibly too fully covered, and that some matters which might have been omitted from an introductory text-book have necessarily received too brief a treatment; but this fault—if such it be—is counteracted by the references to other works in which the subject is more fully dealt with. These references to previous literature add very greatly to the value of the work; not large in number, they are very judiciously selected, form a satisfactory basis for advanced study in all branches of the subject, and, without exception, are such that no one wishing for a mastery of the subject could afford to leave them unstudied.

R. D. O.

Chemical and Physical Constants.

Handbook of Chemistry and Physics. A Ready-Reference Pocket Book of Chemical and Physical Data. By Prof. C. D. Hodgman, assisted by Prof. M. F. Coolbaugh and Cornelius E. Senseman. Eighth edition. Pp. 711. (Cleveland, Ohio: Chemical Rubber Company, 1920.) 3 dollars.

THIS compact little volume contains a vast array of chemical and physical constants. Since the first publication in 1914 it has passed through eight editions in the United States—a sufficient proof of its utility as "a comparatively comprehensive reference book for use in the laboratory or classroom."

The tables on the properties of inorganic and organic compounds are very complete, and chemists will appreciate particularly the tabular information on the solubility of inorganic salts in water. The data on the "Dehydration of Metallic Sulphates" and the "Decomposition of Anhydrous Metallic Sulphates" are distinctly novel features. In the qualitative analysis scheme it is somewhat difficult to follow out the behaviour of chromium. A very complete table is given of heats of formation and solution, but it is to be regretted that no indication is given as to the sources from which the data have been compiled.

The section devoted to physics is fairly complete, and one notes with pleasure that the table for the reduction of psychrometric observations refers to the ventilated type of wet and dry bulb thermometer only. At the end of the volume eight pages are devoted to problems, the utility of wh h in a book of data is doubtful.

The book has some blemishes, for the most trustworthy data have not always been chosen. To take one example only, in the table of "Fixed Points for High Temperatures" the melting point of nickel is given as 1427° and that of platinum as 1775°. Ten years ago the Carnegie Institution published a memoir on High Temperature Gas Thermometry, and the values

there given (1452° and 1755°) have since been almost universally accepted. Also, in view of the thorough work of Prof. Callendar on the specific heat of water, it is somewhat surprising to find that the values given are "the mean of various determinations, including Calendar and Blonsfield, 1912"; one frequently observes that the names of observers are misspelt as in this quotation.

It is hoped that before the next edition is issued the various sections will be submitted to expert scrutiny, for the value of the book would be greatly enhanced if the user could feel sure that the most trustworthy data are quoted. E. Griffiths.

Our Bookshelf.

Illustrations of the Flowering Plants and Ferns of the Falkland Islands. By Mrs. E. F. Vallentin. With descriptions by Mrs. E. M. Cotton. Pp. xii+64 plates+text+ii. (London: L. Reeve and Co., Ltd., 1921.) 84*s.* net.

Since the publication of Sir J. D. Hooker's "Flora Antarctica" much progress has been made in the study of the Falkland flora and from a taxonomic standpoint it may now be said to be well known. Nevertheless, a well-illustrated compact flora has been a desideratum and it is thus additionally unfortunate that owing to a serious breakdown in health the completion of Mrs. Vallentin's work has been indefinitely postponed. The volume now under notice contains 64 plates illustrating in colour, and with excellent dissections, many of the most characteristic Falkland plants. Each plate is accompanied by a short description of the family, genus and species. It seems a pity that with the space available fuller descriptions and more detailed ecological notes have not been provided. The repetition of the description of the family appears to be unnecessary; thus the same diagnosis of the Compositæ is repeated eleven times.

The work as a whole illustrates many of the essential features of the Falkland Islands flora. The predominance of dwarf herbaceous and subshrubby perennials, especially characteristic of steppe and heath formations, is emphasised both by the plants chosen for illustration and by the small number of therophytes and the absence of phanerophytes, except for a few nanophanerophytes.

We have no doubt that this work will prove most useful to inhabitants of the Falkland Islands who take an interest in the natural history of their country by enabling them to identify easily many of the common plants around them, and that it will also be used in a more general manner by workers in systematic and geographical botany in other countries.

W. B. Turrill.

The Microscope: Its Design, Construction and Applications. A Symposium and General Discussion by many Authorities. Edited by F. S. Spiers. Pp. v+260 +plates. (London: Charles Griffin and Co., Ltd., 1920.) Price 21*s.* net.

The addresses and papers given in 1920 at the conjoined meeting of the Faraday, Royal Microscopical, Optical and Photomicrographic Societies and Technical Optics Committee of the British Science Guild are gathered together conveniently in the volume under notice. All the papers are by specialists in their respective branches and the whole constitutes a valuable contribution to microscopical science. The President, Sir Robert Hadfield, in his introductory address traced the history of the development of the microscope, and papers on the earliest steps in the invention of the microscope and on the history and design of photomicrographic apparatus are contributed by Dr. Singer and Mr. Martin Duncan respectively. The future of the microscope is dealt with in suggestive papers by Mr. Barnard and Mr. Schneider, while Profs. Cheshire, Conrady and Porter discuss the mechanical design and optics of the instrument. Many experts in their particular subjects give practical details on the application of the microscope in fermentation industries, in petrology, metallurgy, engineering and metrology. Methods of illumination, the testing of objectives, and optical glass and its manufacture are other subjects dealt with. In addition to the papers themselves, a summary of the discussions following their reading is included and the volume is illustrated with many plates and figures. The work, which has been ably edited by Mr. Spiers of the Faraday Society, is indispensable to any one desiring to follow the trend of the modern developments of the microscope and of microscopical science. R. T. H.

Introduction to the Study of Minerals and Guide to the Mineral Collections in Kelvingrove Museum. By Prof. P. MacNair. Second edition. Pp. viii+94+1 plate. (Glasgow: Hay Nisbet and Co., Ltd., 1921.) 1*s.*

Prof. MacNair is to be congratulated on having introduced many improvements in the second edition of his useful guide-book. The figures illustrating the crystal-forms are much more accurate than those published in the first edition, though there are still a few which should have been replaced. The part dealing with crystallography has been much increased and the systems have been subdivided into groups, the introduction of which in place of the classes of the accepted systems of crystallography is rather confusing.

The guide includes a clear account of the optical and other properties of minerals, a description of some of the commoner species, a glossary of terms, and a list of species in the collection. The book is based very much on the lines of Fletcher's "An Introduction to the Study of Minerals," of which the fifteenth edition is still used as the guide to the Mineral Department of the British Museum (Natural History). It will be noted that Prof. MacNair in Glasgow has produced his book at sixpence less than the price of the British Museum Guide.

The Secrets of the Self. (*Asrár-I Khudi.*) A Philosophical Poem. By Sheikh Muhammad Iqbal. Translated from the Original Persian with Introduction and Notes by Dr. R. A. Nicholson. Pp. xxxi+147. (London: Macmillan and Co., Ltd., 1920.) Price 7*s.* 6*d.* net.

This poem has an interest beyond that of its artistic form or æsthetic content, for it reveals the effect on the oriental mind of contact with the culture and philo-

sophy of the West. The writer is a firm and devout believer in Mahomet. He has studied Bradley and Bergson, he has taken degrees at Cambridge and at Munich, and he has returned to Persia, more ardent than ever in the vision of a world-triumphant religion, an Islamic kingdom of God on earth.

Proceedings of the Aristotelian Society. New Series—vol. xxi. Containing the papers read before the Society during the Forty-second Session, 1920–1921. Pp. iv.+246. (London: Williams and Norgate, 1921.) 25*s.* net.

ALTHOUGH the papers in this volume are philosophical in the technical meaning, several of them are of unusual scientific interest, and all of them show how the results of pure scientific research are influencing philosophical speculation.

Prof. Montague's paper on "Variation, Heredity and Consciousness" is described as a mechanist answer to the vitalist challenge. It develops an ingenious theory according to which it is possible to trace the transformation of the potential energy acquired by the brain, through the kinetic energies of sensory nerve currents, into all the phenomena of mind and consciousness. In the whole process no factor is admitted which is not definable in purely physical terms. The Dean of St. Paul's in his Presidential address "Is the time series reversible?" finds it impossible to keep out Einstein and the principle of relativity. Miss Oakeley gives an excellent critical account of the recent work of Prof. Driesch in "Philosophy of Life and Knowledge." Prof. Boodin in a paper on "Cosmic Evolution" deals with the new theories of the origin and evolution of life of the American biologists, Osborn, Willard Gibbs and Henderson. Dr. Dorothy Wrinch's paper "On the Structures of Scientific Inquiry" is abundantly illustrated with examples from modern research in mathematics and physics.

Tables of Refractive Indices. Vol. xi. *Oils, Fats and Waxes.* Compiled by R. Kanthack. Edited by Dr. J. N. Goldsmith. Pp. 295. (London: Adam Hilger, Ltd., 1921.) 25*s.* net.

IT is satisfactory to find a British firm of scientific instrument-makers not content with manufacturing instruments but, in addition, providing facilities for the compilation and publication of data which will facilitate the use, and incidentally lead to the extended employment of their manufactures. Mr. Kanthack has done his work well, and no one who uses his tables is likely to complain that oils of any importance have been omitted or that the figures quoted are badly selected from those available.

The names of the oils are arranged alphabetically, both native names and scientific names of the sources being given. Wherever possible the constants are quoted beside the native names and cross-references placed against the scientific names. This has two disadvantages: native names are variable, being usually merely attempts at phonetic renderings of native pronunciations and they also vary with the country of origin. Further, the method of arrangement fails to bring together oils which are similar in character, a matter of some importance for convenience of reference. It would be difficult if not impossible to devise an arrangement to obviate these disadvantages entirely, but it would probably improve matters somewhat if the scientific names of the sources of the oils were made the backbone of the arrangement and the native names given in a separate glossary.

The value of the tables to the analyst is enhanced by the inclusion, in separate appendices, of refraction constants for glycerol, glycerides and fatty acids, and "hardened" and polymerised oils, with approximate temperature corrections and factors for the inter-conversion of refractive indices and butter refractometer readings. There is also an extensive bibliography.

T. A. H.

The Distribution of Vegetation in the United States as related to Climatic Conditions. By B. E. Livingston and E. Shreve. (Publication No. 284.) Pp. xvi+590+plates. (Washington: Carnegie Institution). 9 dollars.

THE development of ecology has been much stimulated in recent years by the detailed and exact work of American botanists. The book under notice forms in many respects a companion volume to that of Clements on "Plant Succession." Essentially it deals with the delimitation of vegetational areas in the United States and the relation of these to environmental conditions. Prof. Livingston is well-known for his work in plant physiology, as well as in ecological plant-geography, and Dr. Shreve is also a physiological ecologist. So this aspect naturally dominates in their joint work.

The introduction and the first portion of Part II., dealing with environmental conditions, will be read with interest by all ecologists and physiologists since they contain much useful general information and new standpoints for the survey of old questions. That portion of the book which deals directly with American vegetation shows clear indications of an enormous amount of detailed work. The abstraction and preparation of figures and tables illustrating the very varied climatic conditions of the United States and their correlation with vegetational areas must have necessitated much concentrated labour, and co-nationals of the authors will owe a debt of gratitude to them for the results. Numerous outline maps are reproduced to show graphically the distribution of climatic conditions, vegetational types, and even occasionally of single species. One coloured map showing the vegetational areas of the United States, and another the life-zones, accompany the volume, which is also provided with a table of contents but no index.

Modern Motor Car Practice. Edited by W. H. Berry. (Oxford Technical Publications.) Pp. xii+582. (London: Henry Frowde and Hodder and Stoughton, 1921.) 31*s.* 6*d.* net.

A LARGE amount of information regarding the details of motor cars and their working in practice will be found in this volume. As a rule, each principal detail, such as clutch, steering gear, etc., forms the subject of a separate chapter. Different designs are discussed and their defects and advantages indicated. The book

is profusely and well illustrated, and forms a valuable compendium for car users. The designer will also find it useful from the same point of view, but as the treatment is non-mathematical throughout, its service to him will be somewhat limited. Whilst the volume is for the most part free from errors, there are some statements regarding resiliency on p. 376 which require revision. The book is up-to-date in general, and includes a chapter on the X-ray examination of materials and another on welding repairs.

My Electrical Workshop. By F. T. Addyman. Pp. viii + 249. (London: The Wireless Press, Ltd., N.D.) Price 7*s.* net.

DESPITE the many complete mechanical contrivances now obtainable which enable boys to construct models by simply using a screw-driver, there is still a large number who prefer to make things for themselves. Those who have inclinations towards electricity will find the volume under notice useful in helping them to produce apparatus which will work and can be made from simple materials, provided they possess some measure of handiness with tools. There is a large number of illustrations which assist in making the text clear, and here and there the real article is described as well as a method of making a model having the same principle.

A Manual of Pharmacology. By Prof. W. E. Dixon. Fifth Edition, completely revised. Pp. xii + 468. (London: Edward Arnold and Co., 1921.) 18*s.* net.

SINCE the publication in 1905 of the first edition of Prof. Dixon's "Manual of Pharmacology," the volume has maintained its reputation as one of the foremost works on the subject, a reputation which it gained by the very practical arrangement of the subject matter and the readily intelligible manner in which it was presented. The fifth edition retains those characteristic features. Very little change has been made in the classification of the drugs discussed; they remain as before in pharmacological groups.

The chief alterations that have been made consist in the insertion of new paragraphs where necessary and in the correction of the text so as to give effect to the results of work that has been carried out by the author and others during the last few years. Several drugs, such as agaricin, allantoin, etc., to which attention has recently been directed, are accordingly considered. Chemotherapy, the conception that the protoplasm of the living cell is provided with receptive side chains to which drugs can attach themselves and so bring the poisonous properties of a toxophore grouping to bear, is, in the author's opinion, based neither on chemistry nor on pharmacology. By the slow oxidation of salvarsan in the blood into a substance containing trivalent arsenic a steady supply of efficient parasiticide is thrown into the blood, the action of the salvarsan being thus only indirectly on the parasite. On the other hand, in the treatment of filariasis, bilharzia and kala-azar by the intravenous injection of soluble antimony salts, these apparently penetrate the embryos or adult parasites and so produce their toxic action. Of the value of twilight sleep in depriving labour of its terrors, Prof. Dixon is by no means convinced; in his view it has still to be determined.

The section on antiseptics and disinfectants has been practically rewritten. The action of hypochlorites on proteids and the antiseptic action of chloramines and their sodium compounds as well as of flavine are concisely but very clearly described. The employment of sunlight, ultra-violet rays, X-rays, and radium emanations as remedial agents is also briefly discussed. There is no doubt that to the student and to the practitioner of medicine, as well as to all who are interested in pharmacology, Prof. Dixon's "Manual" will remain indispensable.

Atomic Theories. By F. H. Loring. Pp. ix + 218. (London: Methuen and Co., Ltd., 1921.) 12*s.* 6*d.* net.

RECENT investigations on the structure of the atom and allied studies have proceeded so rapidly that it is difficult for the average reader to keep pace with the advances. The subject is, however, of absorbing interest, and has such an important bearing on all branches of physics and chemistry, that every student feels the need of making himself acquainted with the main features of the new theories. In the case of chemical students, a non-mathematical treatment is, so far as is possible, desired. Mr. Loring's book, which is attractively printed on good paper, will be found of great interest and value in this connection. Particular mention may be made of the accounts of Rutherford's theory in Chapter VIII. and of Bohr's theory in Chapter X. In some cases, notably Chapter IX., on the Quantum Theory, the treatment is too condensed to be clear. The style in many respects is often at fault; the author shows a tendency to wander in sentences, which leaves one with a confused idea of what he is trying to say. The statements on pp. 6 and 15 that fractional atomic weights ($O = 16$) are due to isotopes cannot be maintained in the face of examples such as iodine and nitrogen.

East Carelia and Kola Lapmark. Described by Finnish Scientists and Philologists. By T. Homén. Pp. xiv + 264. (London: Longmans, Green & Co., 1921.) 21*s.* net.

THE separatist movement in Eastern Carelia dates from the Soviet *régime* in Russia. It has now led, on the one hand, to a Soviet attempt to suppress it by force, and on the other to an appeal by the Carelians to the League of Nations. The present volume, which was originally published in Finnish and later in Swedish, is in a sense a contribution to that movement in so far as it aims, in a series of papers written by experts, to give an account of the country, its products, history, and inhabitants. For this purpose Kola Lapmark, where the Carelians are not in a majority, is included. It was written before the Treaty of Dorpat, 1920, by which a strip of Russian territory ending in Pechenga Gulf was ceded by Russia to Finland, thus disposing effectively of Finnish claims to Kola Lapmark. The propagandist aim of the book, however, does not obtrude and is mentioned only rarely. The volume is a valuable contribution to the geography of Arctic Europe, and is well illustrated by several maps.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Research Degrees and the University of London.

THE question of research degrees in the University of London, which is the subject of a letter by Dr. Morley Davies in NATURE of February 23, p. 238, raises an important matter of principle. The proposal of the sub-committee of the Academic Council of the University to institute a new series of examinations for the M.Sc. degree, appears to have arisen from a desire to secure uniformity in the granting of the degree. Whether it will do so or not is a matter of opinion, but, in any case, many people consider that such uniformity can be obtained only by retrogressive steps, in view of the urgent necessity for the training of research workers.

The examination fever has fortunately died down in recent years. The general raising of the standard of examinations which has accompanied the rapid advances in natural and experimental science has resulted in the Honours B.Sc. Examination becoming not only a searching test of the general knowledge of the principal subject chosen by the candidate, but a severe test of his familiarity with some special branch. Beyond the standard thus set, it is very difficult for an examiner to impose a test without giving a candidate a choice of a large number of highly technical questions either limited in scope or controversial because of the generalities in which they tempt candidates to indulge. Such a type of examination almost puts the examiner at the mercy of an examinee who has the wit to ask in an apostrophic way, "What did Gladstone say in 1876?" or to refer to the rocks of the Amazonian forests or the flora of the Senussi country!

Ostensibly, the undesirability of having four standards of research for the B.Sc. (research), M.Sc., Ph.D., and D.Sc. disturbs the sub-committee. Dr. Davies has dealt effectively with this question. Leaving aside the B.Sc. by research as a qualification granted but rarely and exceptionally, no difficulty as regards the standard for the other three degrees will arise in the mind of many examiners.

May I submit the following as a purely suggestive general scheme of minimum requirements? The candidate should in his M.Sc. thesis show that he is familiar with the literature of his branch of research, and able to summarise and analyse that literature effectively; further, that he has had sufficient originality of mind to pursue a line of inquiry instituted by others, and to extend knowledge in such a direction. For the Ph.D. degree he should be able to make a marked contribution to the advance of knowledge, and to submit a finished account of an investigation or an interim report, complete so far as possible, and containing legitimate deductions, his dissertation bearing evidence of the expenditure of an appropriate amount of time and labour. For the degree of D.Sc., it is desirable that the candidate should display great originality of mind and a capacity for research of a high order. He should be able not merely to use the methods and weapons of others, to extend their fields of investigation and apply their results, but to evolve methods and tools of his own, strike out into new paths, and in turn give a lead to less experienced workers.

If some such distinction as that drawn above is not, even unconsciously, adopted, the matter of the respective standards for the Ph.D. and D.Sc. is likely to become chaotic. If the M.Sc. by examination is instituted an undesirable tendency, already in evidence, for the candidate to proceed direct from B.Sc. to Ph.D. (and there remain) will undoubtedly develop.

As an illustration of an opposite point of view to that taken by the sub-committee, I may perhaps be allowed, without advocating in any way too early specialisation, to commend the scheme adopted in this university of allowing a student (by arrangement of the head of the department concerned) to present, as an alternative to taking one special paper in the Hons. B.Sc. Examination, a report upon some piece of investigation carried out by him.

P. G. H. BOSWELL.

University of Liverpool, March 7, 1922.

Phenological Observations.

THE highly interesting communication of Mr. J. E. Clark in NATURE of February 16 directs attention to some important problems in phenology, and I beg space to indicate one or two that have more especially occurred to me.

First, in the comparison between England S.E. and England S.W., I do not think the earlier flowering of horse-chestnut (*Æsculus hipp.*) around London than in Cornwall is at all a surprising result, inasmuch as the climate of Cornwall with its rough sea gales is notoriously unfavourable to trees (except, perhaps, in the deeper valleys) as distinct from herbaceous plants. It may also be that the more rapid rise of temperature in the south-east of England than in the oceanic south-west peninsula acts as a stimulus to the spring flowering of certain trees.

Secondly, I am anxious to urge the desirability of correlating the autumnal phases with the spring phases of vegetation in studying the effects of climatic conditions upon the seasonal phenomena of plants. Let me illustrate the point by an example, that of our native oak (*Quercus robur*). According to Hopkins's "bio-climatic" law, the oak should burst into leaf and flower a week to ten days sooner in southern than in northern England, and this certainly agrees pretty well with general experience. But is it safe, therefore, to infer that because the oak puts forth its leaves a week or so earlier in the south of England in response to a warmer climate, it will shed them a week *later* in response to the same? Consider the opposing factors that appear to be at work. In studying individual oaks of the same locality in diverse parts of the country I have constantly noticed that those trees in autumn which are in full tint, or are half bare, are usually such as have already ripened their acorns, whereas those of which the leaves are still green have not yet matured the acorns.

Now if one may apply this generalisation to the comparison between the north and south of England it would appear that, on the one hand, colder climatic conditions will tend to cause earlier defoliation in the north, and, on the other hand, that internal biological conditions will tend to delay defoliation in order that the acorns, the flowers of which were ten days behind the south to commence with, may be brought to maturity. But the generally more inclement conditions in the north, with the earlier night frosts, are impatient of any delay in the fall of the leaf, and it becomes a question of the utmost interest how the average dates of defoliation in the north and south of England actually do compare with those of foliation. One knows that the northern limit of the British oak as a flourishing species is set somewhere about the middle of Scotland, and presumably the critical determining fact is a summer too cold and short for fructification.

Thirdly, in the complex study of phenology the influence of factors other than meteorological should ever be borne in mind, as was brought to the attention of the Royal Meteorological Society last year by

Dr. E. J. Salisbury in a paper published in conjunction with the Phenological Report for 1920 (Q.J.R. Meteor. Soc., October 1921).

The average dates of leafing, flowering, etc., of a particular species is the result of *prolonged* adaptation to climate, and whilst the deviations of particular individuals from that date is controlled in part by local conditions of habitat, etc., the deviations of the same individuals in different years are governed not only by the weather of the current season but also by that of the previous season. The deviations from year to year are really kept within remarkably narrow limits, and there can be no doubt that force of habit is all-important in causing the periodic processes of vegetation to occur as near to the same dates year by year as external meteorological vicissitudes will permit. L. C. W. BONACINA.

The Resonance Theory of Hearing.

DR. PERRETT will, I hope, excuse me if I have seemed to impute absurdities to him (NATURE, February 9, p. 176). My reason for replying to his letter was because it seemed to me unfair to the resonance theory to leave his criticism unquestioned. But perhaps the consideration of an example will help to bridge the difference of opinion between us. Prof. Millar in his "Science of Musical Sounds" has given, on p. 201, analyses of the intensities of the harmonics of the oboe and clarionet. Whereas the clarionet note has harmonics of which the 8th, 9th, and 10th are the strongest, in the oboe note, on the other hand, the 4th and 5th harmonics have the greatest intensity If, then, the ear heard both these instruments sounding the same tone at one and the same time, it would hear one fundamental accompanied by strong 4th, 5th, 8th, 9th, and 10th harmonics.

Now no musical instrument of which Prof. Millar gives the analysis has these harmonics strongly marked, and the chances are enormously against any *one* musical instrument whatever having precisely the same intensities of the harmonics as those of the oboe and clarionet sounding the same tone together. In other words, there is something quite unique about the harmonics in the case that I have taken, which should enable the observer to say that the sound is to him not like an oboe only, or a clarionet only, but as if an oboe and a clarionet were speaking the same tone at the same moment. Now I do not say that the ear can never be deceived, for Helmholtz himself showed that vowels even, can be imitated by means of tuning-forks, but it seems to me that the characteristic intensities of harmonics do in almost all cases enable an observer to recognise the sounds of different classes of musical instruments even when any two of them are playing the same tone. Let us turn finally to the case which Dr. Perrett mentions, namely, when the voice is accompanied by the same tone produced by the chattering teeth. We know from the works of Helmholtz, Millar, and many others that the voice overtones have one maximum of intensity for the vowels "o" and "a" and two maxima for "e," "i" and "u," other overtones being very weakly represented. We also know that discontinuous sounds, such as those produced by tooth striking tooth, are very rich in overtones, and that these do not occur in maxima in any definite way. We should, therefore, expect the voice and the teeth-sound to have overtones very different in their intensity distribution. Therefore the observer should, so far as one can judge, hear overtones as characteristic on which to base his judgment, as those given out by oboe and clarionet.

I must, therefore, repeat that, in my opinion, Dr. Perrett is mistaken in his objection to the resonance theory. H. HARTRIDGE.

King's Coll., Cambridge.

Snow Furrows and Ripples.

WHILE at Gstaad recently, after a fine fall of snow (about 24 inches), the Föhn blew and rain fell for some hours. The weather then cleared, the temperature falling below freezing-point, and the snow then presented the appearance shown on the accompanying picture (Fig. 1). The peculiar "silloné" appearance of the snow on the slopes is very striking. It looks as though water had run down over the surface, but this did not happen during the rain or afterwards.

FIG. 1.

As to the origin of the "furrows" (sillons), I think they were caused by contraction of the snow, as the gentle rain wet the fine-grained snow particles and drew them together. I observed afterwards the same development of furrows during fine weather on sunny slopes. These were so shallow that I failed to photograph them, but the whole hillside was covered with them. I also noticed that they occurred on the low-lying flat meadows, although they had no particular orientation in that case and occurred in every direction. This may be discerned in the lower parts of Fig. 1. E. C. BARTON.

I WAS once out on the snow-covered prairie at Moose Jaw, Saskatchewan, when suddenly, the hot chinook wind began to blow, the counterpart of the Alpine föhn. The snow melted away with astonishing rapidity, and very soon there was the sound of trickling water, which I had not heard for months, for the season was late winter. The melting was not uniform, nor did it produce longitudinal furrows, but on the contrary a rippled structure of ridges and furrows transverse to the wind, adding yet one more variety to the many kinds of ripples which I had seen in snows of different consistency.

VAUGHAN CORNISH.

Historical Notes upon Surface Energy and Forces of Short Range.

By W. B. HARDY, Sec. R.S.

THE following notes were completed about fifteen years ago for a purpose not now likely to be fulfilled. They seem worthy of publication because the early history of the subject, which is to be found in Clerk Maxwell's essay on "Capillary Action,"[1] and is based upon a report made by Challis to the British Association in 1834, seems to be wrong in material points. Challis does less than justice to the eighteenth-century philosophers.

According to Poggendorff, Leonardo da Vinci must be considered as the discoverer of capillary phenomena, but a fact so patent to all can scarcely have been discovered by a single man. The ascension of water and other liquids in capillary tubes was "noticed by the Academy del Cimento at Florence early in the seventeenth century, but seems not to have been much regarded in the sequel."[2] Communications to that academy were anonymous. Probably Leslie's authority was "une anecdote curieuse qui a été publiée par M. Nelli ('Saggio di storia letteraria,' etc., p. 92) sçavoir que le véritable auteur de cette expérience fut Nicolas Aggiunti, mort le 6 décembre, 1635 . . . l'un des Fondateurs de l'Académie del Cimento."[3]

The beautiful volume issued by the Academy in 1667 is devoted mainly to experiments in a vacuum. Amongst these is a demonstration of the rise of fluid in a capillary tube *in vacuo*.

The phenomenon was still novel when Boyle demonstrated capillary rise "to the no small wonder of various mathematicians."[4] Boyle tried, but failed, to observe whether the rise took place in a vacuum, and he also inquired why the capillary surface should be concave with water and convex with mercury.

If Leslie is to be trusted, the revival of the subject was part of that great revival of physical experiment which followed the promulgation of the Newtonian system at the close of the seventeenth century. At any rate, though Hauksbee was the first whose published work needs consideration, he was not the first to make experiments, for he writes of many attempts to "solve this Appearance. . . . Some have argued from the impeded or diminished Action of the Air,[5] others from the Innixion or Resting of the Parts of the Fluid on the Pores and Asperities of the Glass; others again from the Congruity and Incongruity of the Parts of Matter one to another."[6]

Argument was direct and frequently personal in the pamphleteering times of the eighteenth century, and Hauksbee goes on to say that the "First two ways of solving the Difficulty have this advantage above the other, that they are perspicuously False; whereas this latter is more mysteriously so . . . because of the hard Words of Congruity and Incongruity."

Nothing tangible has survived from these earliest discussions, and we begin the subject with Hauksbee, whose merit was twofold; he was an exact experimenter, and he succeeded in interesting Newton in the problem. His first paper appeared in the Philosophical Transactions for 1709. This led Newton himself to make experiments, and it is a nice question how far the speculations concerning the constitution and intimate forces of matter which appear in the incomparable[7] thirty-first query are owing to his attention being thus directed to the problem of cohesion. The thirty-first query appeared for the first time in the second edition of the "Opticks" of date 1718. Be this as it may, though exact experiment and induction begin with Hauksbee, what may be called in eighteenth-century phrase the philosophy of the subject begins with Newton.

Hauksbee experimented with capillary tubes and also on the rise of fluid between planes of glass, marble, and metal. As fluids he used water, alcohol, and various oils. He noticed that the phenomenon of the rise of fluid in small spaces is not peculiar to one fluid or one solid, and that it is not due to the presence of air, since the rise occurs in a vacuum. His most important experimental result was that the height to which fluid rises is the same in two tubes of the same diameter, but one "at least ten times as thick as the other." Comparing this with the magnet, which can be broken into smaller and smaller pieces each of which will exert the force, he argues that the attraction of the solid for the fluid is limited to the surface of the solid.

There the matter was allowed to rest so far as the paper of 1709 is concerned. In the paper of 1711 the movements of a drop of oil of oranges between two glass planes inclined to one another at an angle are rightly referred to variations in the area of the surface of contact between fluid and solid, but the statement that the power of attraction must increase in proportion to that surface cannot now be defended. His papers of 1712 and 1713 are devoted to careful measurements of the curves which the surface of water forms when enclosed between glass planes. Brooke Taylor in 1712 had already pointed out that the curve was an hyperbola.

There is little theory in Hauksbee's papers. He was essentially an experimenter,[8] but in his book he draws certain definite conclusions from his experiments for which he has not received due credit.

"That very great Man, Sir Isaac Newton (the Honour of our Nation and Royal Society), has set both these Laws of Attraction in a very clear Light"—namely, that amongst the greater bodies of the universe the attraction decreases reciprocally as "the Squares of the Distances do encrease," and that the smaller portions of matter tend to each other by a law very different and unknown, but one according to which the "attractive Forces do decrease in a greater proportion than that by which the Squares of the Distances do encrease." Hauksbee then goes on to make this

[7] "Our Incomparable President," Jurin, 1718. Also Halley wrote concerning the "Principia" in 1686, "an incomparable treatise on motion."
[8] "There's no other way of Improving Natural Philosophy but by Demonstrations and Conclusions, founded upon Experiments judiciously and accurately made."

perfectly definite statement that "the attractive Power of small Particles of Matter acts only on such Corpuscles as are in contact with them, or removed but infinitely little Distances from them," thus anticipating Segner by nearly half a century.[1]

Obviously, it follows that (in anticipation of Clairaut) the water in the interior of capillary tubes is held up by the attraction of the particles of the walls of the tube, to those particles of water at the surface which are "urged strongly towards the Glass." Lastly, Leslie was not the first to show that the attraction is everywhere normal to the surfaces of the solid, as Maxwell states, for Hauksbee says: "The Parts of the Liquid adjoining to the concave Surface of the Tube are strongly attracted by it, and that in a Direction perpendicular to the sides of the Cylindrick Glass."

A comparison of contemporary references with the actual writings of Newton leads to the conclusion that much which is attributed to him was made public verbally during the discussions at the Royal Society. An interesting instance is furnished by the note to Dr. Jurin's paper.[2] At any rate, the hints scattered through the Queries to his "Opticks" as to the existence of forces acting between the particles of matter "which reach to so small distances as hitherto to escape observation," and which sprang in the first instance from his study of the diffraction of light, became a compact body of doctrine accepted in England before 1720. Hauksbee, as we have seen, wrote in 1709, nine years before the thirty-first Query was published, of intermolecular forces of insensible range, which fall off according to some higher power than the square of the distance, and Jurin in 1719 speaks of the "universally acknowledged" attractive force between the particles of a fluid (water), and refers to the sphericity of drops of rain, and the fusion of drops of water when in contact, as examples of the operation of the force; in both cases reference is made to Newton.

This doctrine, which, I believe, was shaped by the discussions at the Royal Society, may be embodied in a series of propositions as follows :—

(1) That, in addition to the force of attraction which acts between larger bodies and varies in intensity according to the inverse square of the distance, there is another attractive force which acts between the ultimate particles of matter, has a range of insensible magnitude, and varies inversely according to some power of the distance higher than the square.

(2) At distances less than a certain minute value this attractive force gives place to a repulsion.

(3) The attractive force "performs the Chymical Operation"; it is the source of cohesion, and cohesion brings about the movement of fluids in small spaces.

(4) Heat is a quality of matter, not a substance. It is the agitation of the particles of matter, and if "the Heat is big enough to Keep them in (adequate) Agitation, the Body is fluid."

(5) The ultimate particles of matter are of definite shapes—not always spheres—and are impenetrable.

Dr. Jurin, secretary of the Royal Society during a portion of Newton's term as president, was led to the subject of capillarity by "an ingenious Friend" who proposed a plausible method for "making a perpetual Motion" founded upon Hauksbee's experiments. The method is of little interest, but Jurin was led directly by it to the discovery that the height to which fluid is raised is determined by the "periphery of the tube to which the upper surface of the water is contiguous," and he argues that, as this is the "only part of the tube from which the water must recede upon its subsiding," it is consequently "the only one which by the force of its cohesion or attraction opposes the descent of the water." Hence the rise must be inversely proportional to the diameter of the tube. Newton and Machin pointed out that Jurin's "'periphery' . . . is really a small surface, whose base is that periphery (of the tube), and whose height is the distance to which the attractive power of the glass is extended."[3]

In the interval between Jurin's papers a book appeared "by a very learn'd and ingenious member of this [the Royal] Society," whose name I have not succeeded in tracing. It deserves mention because in it the effect of the attractive power of the water for itself is exactly considered. Jurin demonstrated the attraction in a striking manner when he showed that if the tube at the lower part of a funnel is drawn out to capillary dimensions and the funnel inverted with the open mouth under water, then if it be filled by drawing water up into the capillary it will remain full. The experiment succeeded in a vacuum. He infers that the lower mass of water in the funnel must be suspended by its cohesion to the column within the capillary. At the end of the memoir is a series of propositions, of which Nos. 4 and 6 assert that the particles of water are more strongly attracted by glass than by each other, but the particles of quicksilver are attracted more strongly by each other than by the glass—hence the rise of water and the depression of quicksilver in a tube.

Though the theories of Hauksbee and Jurin were generally adopted—as, for instance, in the memoirs of Bilfinger[4] and Weitbrecht[5]—there was a body of opinion which contested the existence of attractive forces of cohesion.[6]

The cause of this widespread interest and discussion of capillary phenomena in the eighteenth century cannot be better stated than in the words of the astronomer, de la Lande[7]: "Many phenomena are regarded as allied to those of capillary tubes, . . . *e.g.* the suction of sugar and of sponges, the origin of springs in elevated sites; the secretions in the human body seem to be due to the same cause. . . ." These phenomena illustrate the general attraction of matter, contested too long. "Capillary tubes put into our hands an obvious example of the generality of this law, which is the keystone of physical science." But M. de la Lande's attempts to explain the phenomena were not very illuminating!

In the eighteenth century the force of cohesion was so closely identified with chemical action that Guyton

[1] Maxwell therefore is wrong in saying that "these early speculators . . . do not distinctly assert that this attraction is sensible only at insensible distance."

[5] *Ibid.*, vols. 8 and 9, 1736–37.

[6] *E.g.* Paulian, "Traité de paix entre Newton et Descartes," vol. 3, p. 199; Gerdil, "qui a fait un Livre tout entier contre l'attraction des Tubes Capillaires"; Abat and others. Mairan, who explained cohesion as being due to electrical action, etc.

[7] *Journal des Sçavans* (Amsterdam), vol. 35, November 1768, p. 75. De la Lande, in his system of astronomy, incorrectly refers his own paper to the October number.

de Morveau, for example, in 1773, in his examination of the nature of chemical affinity, attempted to determine the relative affinities of a variety of substances from the force required to detach small plates of glass from their surfaces.[1] The experimental method was investigated mathematically by Laplace and Duprè, and used widely as a means of measuring surface tension.

Though the range of the force of cohesion was recognised as being insensible by these earlier writers, nowhere, so far as I know, did they draw the conclusion that the surface layer of a fluid must be the seat of special forces, though a strong hint appears in Newton's comments upon Hauksbee's experiments. The enunciation of the secondary principle of surface tension was reserved for Segner.[2] Segner appears to have had little or no acquaintance with other work on the subject; he refers only to Clairaut ("Figure de la Terre," 1743), whose book, however, he could not obtain ("quesitum nancisci non potui"): "Cupiebam autem inspicere, propter articulos quasi episodicos . . . rotunditatem guttarum . . . elevationemque et depressionem fluidorum in tubis capillaribus, spectantes. Ea ergo qualia sint, quantumque cum meis consentiant, dicere nequeo." The subject matter of Segner's paper is, in the first instance, the equilibrium of drops of fluid; the equilibrium in tubes is treated from the point of view of the curvature of the free surfaces. The important theorems are Nos. 2 and 3, which assert that if in any drop the volume be divided into a shell, the thickness of which is that of the range of the force of attraction, and an interior mass, the forces on any particles in the latter contribute nothing to determining the form of the drop, but only those forces on any particles in the surface shell which can be resolved along the normal to the surface and in the tangent plane. In his calculations of the effects of the surface tension so produced Segner made the mistake, afterwards corrected by Laplace, of taking account only of the curvature of a meridian section of the drop, neglecting the effect of the curvature in a plane at right angles to this section. To Segner, however, belongs the credit of being the first to deduce the phenomena of capillarity from the surface tension.

The existence of a surface tension was demonstrated objectively when Leidenfrost showed, in 1756,[3] that a soap bubble tends to contract. In 1787 Monge[4] applied the principle to explain the apparent attractions and repulsions between bodies floating on a liquid.

Reference is made by Leslie (see later) to experiments on the subject made in Holland by Musschenbroek. I have not succeeded in tracing these. The only reference in his "Cours de Physique" of 1769 is to the experiments of Hauksbee, and theory is limited to the statement that "l'explication se présente naturellement à l'esprit"![5]

Leslie, in a curiously polemical and pedantic paper,[6] attempts to replace Jurin's "explication" of the rise in capillary tubes, which "is almost universally adopted. It is repeated in all the elementary books of natural philosophy." The attraction of the glass, everywhere normal to the surface and of narrow range, gives rise to an increase in pressure in the layer of water next to the surface of the glass. The result of this pressure is that a drop of water tends to spread out over the surface of the glass and consequently to mount upwards in a tube. "But why should the mere tendency of the water to the surface of the glass occasion a dispersive motion? The reason is that the external particles could not approach without spreading themselves and extending the film: and analogy will instruct us, that the attraction of water to glass must increase in proportion to the proximity of its approach." The liquid film flows up the walls of the tube, carrying with it water which adheres to it, and equilibrium is reached when the weight of the column balances the force by which the film spreads itself over the glass. "This explanation of the action of the solid is equivalent to that by which Gauss afterwards supplied the defect of the theory of Laplace, except that, not being expressed in terms of mathematical symbols, it does not indicate the mathematical relations between attraction of individual particles and the final result."[7] Maxwell gives to Leslie the credit of being the first to explain correctly the rise of fluid in a capillary tube. "He [Leslie] does not, like the earlier speculators, suppose this attraction [of the solid] to act in an upward direction so as to support the fluid directly." Yet a few pages further on Maxwell himself speaks of the tension of the solid as though it intervened actively as an upward pull!

On few subjects has more been written than on capillarity, and yet the exact way in which the attractive forces act in causing the rise of fluid in capillary tubes and the spreading of fluids over solid or fluid surfaces is still obscure. Leslie's account is probably the best, and if true it carries an important corollary—namely, that the layer of fluid attracted by the glass is at least two molecules in depth. Recent writers, if I understand them rightly, would restrict the influence to a layer only one molecule deep.

Leslie's paper is original and powerful, and even now very little out of date. It includes many observations which are still of great interest; of these the only one I have space to mention is the discovery of the fact that the "assimilation" of fluid by porous bodies is accompanied by a rise of temperature. He was, I believe, the first to detect this fact.

In the early years of the nineteenth century the subject received attention at the hands of two remarkable men—Dr. Thomas Young and the Marquis de Laplace. Their methods were entirely dissimilar. Young founded his theory on the principles of surface tension, or "superficial cohesion," as he calls it. "Since the time of Segner," he says, "little has been done in investigating accurately and in detail the various consequences of the principle." He begins by making two assumptions—the first, which he attributes to Monge "and others," that the cohesive attraction of the superficial particles causes the free surface of fluids to "be formed into curves of the nature of lintearïæ which are supposed to be the results of a uniform tension of a substance"; and the second, "which appears to be new," that the angle of contact

of a liquid surface and a solid is constant and characteristic of any given pair of liquids and solids.

If a curved line is equally stretched, the force that it exerts along the normal at any point is directly as its curvature, and the same is true of a surface of simple curvature—*e.g.* a cylindrical surface. When the curvature is double, each curvature has its appropriate effect, and the normal force will vary as the sum of the curvatures. As this sum is the same for all perpendicular directions, the normal forces will be proportional to the sum of the greatest and least curvatures. Since the force is always directed to the centres of curvature it will elevate the fluid in a capillary tube when the surface is concave, and depress it when convex. When the surface is cylindrical and therefore curved only in one direction, as when water rises between two glass plates, the curvature must be everywhere as the height of the volume of fluid. When the curvature is double, the sum of the curvatures must be as the ordinate. This is the relation expressed by Laplace's fundamental equation, and Young's essay[1] contains the solution of most of the cases afterwards solved by Laplace. Peacock, Lowndian professor at Cambridge from 1836 to 1858, the editor of the Works of Young, appends the following note: "In the original essay the mathematical form of this investigation and the figures were suppressed, the reasoning and the results to which it leads being expressed in ordinary language; even in its altered form the investigation is unduly concise and obscure." Clerk Maxwell says of Young's methods of demonstration that, "though always correct and often extremely elegant [they] are sometimes rendered obscure by the scrupulous avoidance of mathematical symbols."

The phrase "scrupulous avoidance" is quoted from Challis and is applicable only to the earlier essays. In the article on cohesion of 1816 and the "Elementary Illustrations of the Celestial Mechanics of Laplace," mathematical symbols are freely used, the analysis being by the method of fluxions. Owing to a charming devotion to Newtonian tradition, English mathematics was at its lowest ebb when Young was a student at Cambridge; the reforms which Woodhouse, of Caius, within a few days of the same age as Young, initiated in the Cambridge School in 1803 bore fruit only in 1817, through the action of Herschel, Babbage, and Peacock. A poor training in antiquated methods and a certain vanity in his powers of "clear and simple explanation,"[2] may account for the way in which Young concealed his mathematics. His spirited indictment of the "algebraical philosophers, who have been in the habit of deducing all these quantities from each other by mathematical relations, making, for example, the force a certain function or power of the distance, and then imagining that its origin is sufficiently explained," and of the geometricians who "convert the formulæ into a curve with as many flexures and reflections as the labyrinth of Dædalus," is of the earlier period[3] and probably traceable to his personal irritation with Laplace, whom he never forgave for a real or fancied appropriation of his (Young's) ideas.

Young proceeds to consider the "Physical Foundations of the Law of Superficial Cohesion." This he finds in the nature of the forces of cohesion. Young's work, and especially his "wonderful speculation," as Rayleigh calls it, as to the magnitude of the pressure in the interior of water due to corpuscular forces, which he puts at 23,000 atmospheres, and the calculation based on this estimate of the range of the cohesive force and the size of molecules, are fully dealt with by that writer.[4]

The beginnings of Laplace's well-known theory are to be found more than half a century earlier in the work of Clairaut.[5] Clairaut, like Laplace, was an astronomer, and his treatise on the figure of the earth consists of a mathematical analysis of the condition of equilibrium of fluid masses. This leads to the proposition that "all the particles of a mass of fluid can be in equilibrium amongst themselves when the force which acts on it is the sum of the attraction which they exercise on one another, (namely) gravity, and the attraction of any body which touches the mass." Capillary phenomena are treated as a special case of the proposition. Clairaut's analysis of fluid equilibrium is based upon a consideration of the forces acting upon an infinitely narrow canal of any figure which traverses the mass. The value of the method is that it leads very directly to equipotential surfaces. In the special case of the rise in a capillary tube the canal starts from the meniscus and ends on the general surface of the fluid.

The force of attraction of glass for water is assumed to be the same function of distance as that of water for itself, and to differ only by coefficients of the intensities. Since the range of the force is small (not insensible), only the integrals of the attractive forces about the ends of the tube need be considered. The sum of these must balance the difference in the weight of the limbs of the capillary tube.

The integral of the forces acting on that end of the tube which is at the general surface of the fluid will clearly be equal and opposite to that of the forces on the fluid below the tangent plane to the meniscus; therefore the weight of the column within the capillary is supported by the whole attraction of the fluid of the meniscus above the tangent plane, and of the lower end of the glass tube on the parts of the canal within its range. This result differs from that of Laplace because, though Clairaut assumed the range of the force of attraction to be small, he did not make it insensible. Had he done so he would have got rid of the attraction of the lower end of the capillary tube on the axial canal and have arrived at substantially the same result as Laplace.

Many workers contributed to the subject in the nineteenth century. The curious may find a brief summary of their experiments and conclusions in the papers by Charles Tomlinson which appeared, mainly in the *Philosophical Magazine*, between the years 1870 and 1880. Specially interesting are the speculations from those of Volta onwards as to the cause of the movements of particles of camphor and of other volatile solids on water. Challis's account of Gauss's important memoir cannot be bettered. The substance of it is reproduced by Clerk Maxwell in the article on capillarity which he wrote for the "Encyclopædia Britannica."

Parasitic Worms of Man and Methods of Suppressing Them.

By Major F. H. Stewart, Indian Medical Service (Retired).

One of the most interesting and important groups of the animal kingdom is that of the parasitic worms or helminths; interesting from the point of view of pure science on account of the intricate and varied nature of their life-histories and biological relationships, and important from the effects which they produce on the health of man, domestic animals, and cultivated and useful plants. In the present article a summary is attempted of the results of modern research on the helminths attacking man alone.

The more important helminths attacking human beings can be grouped as follows: (1) the intestinal worms, such as the roundworm and the hookworms, (2) the trematodes or flukeworms, and (3) the filarias and their allies, which live in the connective tissues.

The roundworm (*Ascaris lumbricoides*) and the hookworms (*Ancylostoma duodenale* and *Necator americanus*) live in the small intestine of man. The former is an animal of considerable size, from 20 to 35 mm. in length, while the latter two are smaller, 10 to 13 mm. long. The sexes are separate in all of them, and the females pour out a stream of eggs which are passed out of the human body in the fæces. The eggs ultimately find their way to the surface of the soil, and if the conditions are favourable—*i.e.* if the ground be moist and the temperature not less than that of a European summer (for Ascaris) or of an Egyptian summer (for Ancylostoma)—a small embryonic worm appears within the tough shell. The hookworm larvæ now hatch and lead a free life in mud or in small puddles or pools. Their attack on man is direct and active, for, should the hands or unshod feet come into contact with the mud or water which they inhabit, the little needle-shaped larvæ are roused to great activity. They bore their way through the skin into the subcutaneous tissue, and are carried in the lymph-stream and blood through the heart to the lungs; from the lungs they swim up the air passages and down the œsophagus, so reaching the small intestine. This remarkable life-history was worked out by the Austrian zoologist Looss in Cairo, and, although at first received with some scepticism, it has now been fully confirmed.

In the roundworm, on the other hand, the egg must be swallowed before it will hatch, and this accident (unfortunate from man's point of view) takes place through the consumption of vegetables grown on infected soil, on which eggs have been splashed, or as the result of eating with unwashed hands after working on contaminated land. When the egg arrives thus passively in the small intestine of man, it hatches, and a little larval worm emerges. Until recently it was supposed that this larva remained in the small intestine and simply grew to adult size without further adventure, but the present writer has been able to show that this is not so. The larva bores into the wall of the bowel, enters a vein, and, passing through the liver and heart in the bloodstream, reaches the lungs; from the lungs it migrates to the intestines by a route similar to that adopted by the hookworm.

In the hookworm one object of the migration is obvious, since the larva is merely taking the most sure and direct route to its goal—that is, from the first point at which it comes into contact with man, be this the skin of hands or feet, or of any other part of the body, to the small intestine. It is true that from the finger-tips it might be carried to the mouth and so reach the intestine directly, but only a small percentage of those larvæ which have succeeded in finding man could count on this fortunate chance. By skin penetration, on the other hand, a high percentage should succeed, and it must be remembered that only a few of all the larvæ which have hatched ever succeed in finding man, while only a few of the eggs reach such favourable surroundings as allow the larvæ to form or to hatch.

There is, however, a second object for the migration of the hookworm, the one which is the only motive in the case of Ascaris—namely, that the young larva is not adapted to survive among the strong digestive juices. The young Ascaris lacks not only a stout cuticle, but also that power of chemical defence by which the older parasite resists digestion by its host. Both cuticle and constitutional resistance are developed during the migration, while the larva is being nursed by the blood and lymph, by the bland and nourishing juices of its host. It seems that direct invasion through the skin was the line of attack by the primitive ancestral parasitic worms, and that the present physiological necessity of the migration is due to inheritance.

In geographical distribution *Ascaris lumbricoides* is cosmopolitan, occurring in all lands both temperate and tropical. The hookworms are also very widely distributed, being absent only from the colder parts of the temperate zones. Even there they occur sporadically in artificially warm situations, such as mines and tunnels; the well-known outbreaks of "miners' anæmia," both in the mines of England and the Continent, *e.g.*, in the St. Gothard tunnel, were due to this cause. The proportion of the population affected, especially in the tropics, is extraordinarily high, figures of from 40 to 98 per cent. having been recorded in various countries from the examination of large numbers of the populace. The degree of infestation is highest in the Far East—in China, Indo-China, the Dutch East Indies, and particularly in the tropical Pacific islands. The West Indies and tropical South America also return high percentages, while the southern States of the American Union yield figures which prove that it is not only among dark-skinned races that the parasites become very numerous. Even in Europe 20 per cent of the adult population of Italy and one-half of the children of Central Europe carry the roundworm.

The flukes are flattened oval worms which live in the veins of the abdomen (Bilharzia), in the bile-ducts and gall-bladder (Clonorchis), and in the tissues of the lungs (Paragonimus). Bilharzia occurs over large areas of the tropics and sub-tropics. Three species are known from man, one of which occurs in Mesopotamia, Egypt, and East Africa, the second in Central and South America, the West Indies, and West Africa, and the third in Japan, China, and the Philippines. The association of the West Indies and South America

in one geographical area with West Africa also occurs in the distribution of *Necator americanus*, but is due, not to an old Atlantic connection between the two continents, but to the spread of African parasites to America by the slave trade. In Egypt more than one-half of the population are affected by Bilharzia. Clonorchis and Paragonimus are limited to the Far East—Indo-China, the Philippines, China, and Japan.

The life-histories of all the flukes are similar. The eggs are passed out with the fæces, and if they reach water, the embryos which they contain emerge and swim about actively in search of some particular small mollusc (the intermediate host) into which they must penetrate in order to undergo their first metamorphosis. The intermediate hosts are different in various countries, and for the several worms concerned; for Bilharzia, in the Far East, it is the small water snail, *Katayama nosophora*. This fact was first established by Miyairi and Suzuki, and was confirmed by Leiper and Atkinson; later Leiper and his colleagues identified the intermediates in Egypt as *Bullinus contortus*, *B. Dybowski*, and *Planorbis Boissyi*. From the snail Bilharzia escapes as a more advanced free-swimming larva, which can bore through the skin of man should he venture into infected waters, and, once within the body, it migrates through the tissues to the veins of the liver and abdomen.

For Clonorchis and Paragonimus the first intermediate host is also a small snail, *Melania libertina*. They do not transfer themselves directly and actively from this animal to man, but to a second intermediate—Clonorchis to various species of carp, and Paragonimus to freshwater crabs. In these animals, the second intermediate hosts, they remain passive until they are swallowed by man in food.

The filarias are long, threadlike worms which live in the connective tissues of various regions of the body. They are associated with the disease known as elephantiasis. Geographically they are spread throughout the whole of the tropics. The larvæ circulate in the blood in enormous numbers, and are taken up by blood-sucking insects, in which they grow in size; after the lapse of several days they wander into the proboscis, from which they are injected into the skin of man when the infected insect again feeds. The pioneer work on this subject was done by Manson, and later extended by Low, James, and Leiper. The most important species are *Filaria Bancrofti*, the larvæ of which are carried by various mosquitoes (Culex, Anopheles, and Stegomya), and *Loa loa*, carried by the mangrove fly Chrysops.

The guinea-worm, *Dracunculus medinensis*, is common in India, Turkestan, Persia, Arabia, and tropical Africa. It lives under the skin, and when mature gives rise to a small ulcer, generally on the leg or foot, from which one end of the worm projects. A stream of larvæ is discharged through this ulcer into water when the patient bathes. The next stage of its life is passed in a water flea, Cyclops, and it is by drinking water containing these minute crustacea that man is infected.

Apart from local disease such as abscesses, elephantoid swellings, hæmaturia, etc., the more important helminths produce generalised disease of a very important nature which is surprisingly uniform, whatever be the causal animal. The primary symptom is always anæmia, and the secondary symptoms are such as accompany this condition, namely, general weakness, inability for work or any exertion, disturbance of the heart and circulation, and finally dropsy and death. In mild cases, which fortunately are the most common, the anæmia is not great, and the patient is merely reduced to a lower level of activity, happiness, and efficiency. But when we consider the enormous prevalence of these pests, we can realise the extent of the harm inflicted on mankind by them. It must also be remembered that in most tropical countries the people live only just above starvation level, and that any additional burden will quickly depress them below it. The means by which this anæmia is produced is not clearly understood, but recent work points to the formation of poisonous secretions, toxins, by the worms, which damage both the blood and the blood-forming organs. Bedson has shown that the injection of worm extracts produces acute inflammation of the thyroid, suprarenal capsules, and spleen.

Our armament for offence and defence against these enemies is at present incomplete, but it is becoming more effective. Offensive measures consist in attacking the parasites directly in the bodies of their human hosts, and the main advances have been in the use of oil of Chenopodium against the intestinal worms, Ascaris and Ancylostoma, and the intravenous injection of tartrate of antimony against Bilharzia. The former drug can be used on an enormous scale with great safety and efficiency, and if the inhabitants of a badly infected country can be educated to the point of undergoing treatment *en masse* once a year, a great reduction of disease should result. The second discovery, which we owe to Christopherson, has, at least in theory, entirely changed the future of whole nations. A disease which was previously incurable, and in Egypt, for instance, affects one-half of the people, can now be cured with certainty in a few months. In dealing with ignorant and suspicious native races, however, the rapid adoption of such strange and terrifying methods cannot be expected.

For defensive measures reliance is placed on improvements in sanitation and in the personal cleanliness of the people, advances which will necessarily be slow. No practical means of destroying eggs or larvæ on a large scale in the outer world have yet been discovered. Where an intermediate host exists a reduction of the disease would follow wholesale destruction of, or protection against, the intermediate. In this connection, mosquito destruction has of course already been carried out on a large scale in anti-malaria work in many regions, and it may be extended with the additional object of fighting worm disease. For the destruction of the snails associated with fluke disease periodical drying of canals and irrigated fields has been advocated by Leiper. The knowledge that Clonorchis and Paragonimus are introduced in food should also make the avoidance of these parasites easy.

Three things are above all necessary for the conquest of these plagues: (1) Continued and intensified research into the many points of the intricate life-histories of these parasites and their intermediate hosts which are still obscure; into new methods of destruction, chemical and physical, of both these groups of animals, whether as eggs, larvæ, or adults; and into

new methods of medical treatment for infected man. (2) Systematic instruction and tactful control of the peoples affected. This will be the duty of the medical and teaching professions of the stricken countries. Anyone who has watched the increase of well-taught and capable physicians in such a country as India during the last twenty years will base great hopes on the growth of this influence. (3) And most important, a common and indignant consciousness that these plagues are not inevitable, that by combined effort they can be cast off, and that it is a disgrace to humanity that one-half of its members should be harbouring these loathsome parasites.

The Theory of Relativity in Relation to Scientific Method.[1]

By DR. DOROTHY WRINCH, Fellow of Girton College, Cambridge.

SOME interesting criticisms of the theory of relativity have been advanced recently by M. Paul Painlevé, in two papers in the *Comptes rendus de l'Académie des Sciences de Paris*.[2] M. Painlevé attacks the theory as it at present stands, on grounds which are of general scientific interest. He criticises the expression for ds, the element of length adopted by Einstein,

$$ds^2 = dt^2(1 - a/r) - r^2(d\theta^2 + \sin^2\theta d\phi^2) - dr^2/(1 - a/r),$$

on the ground that it is one of a very large number of forms which satisfy the Einstein conditions. He cites some of the other possible forms for the relation between the length element and the four co-ordinates (r, θ, ϕ, t), and indicates the various consequences which ensue according to the particular form adopted.

At this point we encounter, as M. Painlevé points out, a serious difficulty; but it is a difficulty which is present in all scientific investigations. The botanist plotting on paper the results of experiments which were designed to discover the relation between two variables, x and y, is faced by the same problem when he decides on the method to be adopted in interpolation. For his experiments merely tell him that, whatever the relation between the variables may be, the function connecting them must be such that when $x = x_r$, we also have $y = y_r$, where (x_1, y_1), (x_2, y_2) . . . (x_r, y_r) . . . (x_n, y_n) represent, roughly speaking, the results of his experiments. But the number of his observations is necessarily finite; and it is evident that there are at least as many functions satisfying these conditions as there are points in the mathematical continuum. This difficulty of choosing between a set of functions all of which satisfy the data of the problem presents itself at several critical points of the Einstein theory. It is entirely plain that if science is to be possible, some further principle is required.

THE SIMPLICITY POSTULATE.

In the face of this difficulty, it has been the practice of scientific writers to choose the simplest function available. The question of what constitutes simplicity, or rather the question of when one function is simpler than another, is a difficult one, but in ordinary scientific work, and especially in biology, the term is considered to be well understood. In selecting the simplest alternative, no one, of course, would hold that the other alternatives are impossible. Indeed, the simplicity criterion arranges the various possibilities in serial order. If the first of this set afterwards proves unsuitable, the next one is taken, and so on. Thus, in outline, we may say that the procedure of science is to attach probabilities to the various functions in such a way that the probabilities of functions arranged in order of simplicity decrease rapidly to zero, so that there is little probability of any of the more complicated functions which could be devised being the correct one.

In criticising this procedure from a logical point of view, it will be of no avail to demand, at the outset, a definition of the relation involved in the proposition that one function *is simpler than* another. Common sense uses the notion of simplicity, and we cannot go behind common sense. The business of the logician is to interpret it and relate its various beliefs *inter se*, eliminating when necessary the less fundamental beliefs in favour of those which are held more firmly and the deductions which can be drawn from these beliefs. But this absence of definition makes it important to consider the way in which the simplicity postulate is used in relativity theory. M. Painlevé discusses some of the alternative forms for the length element, to which he sees no objection. He shows that some of them carry with them consequences as to the change in dimensions of a moving body which are mutually inconsistent and in direct contradiction to the Einstein theory. It may therefore be possible to make a choice between some of them by means of data of this kind, and consequently to settle the controversy as to the form of ds, at least to the extent of eliminating those forms which give certain types of change in the dimensions of bodies in motion. M. Painlevé states that he considers some of his forms to be as simple as the form adopted by Einstein. In the absence of a decision being reached by means of further data, the objection of M. Painlevé will fall to the ground only if it is established that the form which Einstein has used for the length element is the simplest one which fits the facts of the external world.

THE VALUE OF COMPREHENSIVENESS.

There is another logical property which enables us to assign a value to rival scientific theories. In choosing between various ways of relating facts *inter se*, we shall evidently prefer theories which group together the largest number of facts under one set of assumptions. Comprehensiveness is, indeed, an important test of the value of a theory, for as the number of facts which are linked together by a theory increases, the theory grows in importance as a

[1] Paper read before the Congress of Philosophy in Paris on December 29, 1921.

[2] "La Mécanique classique et la théorie de la relativité," October 24, 1921; "La Gravitation dans la mécanique de Newton et dans la mécanique d'Einstein," November 14, 1921.

hypothesis, and is of greater value as a guide to the selection of future researches. The recent developments of the theory of relativity due to Profs. Weyl and Eddington are of considerable importance as examples of the value of increasing the range of a theory. Weyl has generalised the geometry used by Einstein in order to produce a function which can conveniently be made to represent the electro-magnetic energy tensor; and Eddington, in accordance with the methodological considerations mentioned above, has suggested still more radical generalisations, with the view of producing, if possible, some function which can be used as an electronic energy tensor. By this we mean a function which contains at least analogues of the main properties of the electron. Towards this very important result Eddington has taken several significant steps, though the physical aspect of this part of the energy of a system, associated with the non-Maxwellian forces, is by no means clear at present. It will obviously be a matter of the greatest importance if it proves possible to cover the electronic phenomena as well as the gravitational and electro-magnetic by a few perfectly definite general assumptions of the same type as those already introduced in relativity theory.

Among the results obtained by Eddington, we may direct attention to the fact that a natural unit of action has made its appearance in terms of which both the energy tensor and the electro-magnetic tensor can be expressed. It appears that this unit of action is 10^{114} times the quantum required in the quantum theory, but the fact that the two energy tensors, which so far have been treated on the lines of world geometry, can be given in terms of the one unit of action may well suggest further developments which may accomplish ultimately the introduction of a tensor to represent the electronic or non-Maxwellian forces.

But let us consider how these advances have been brought about. On Weyl's theory, it is possible that comparisons of length at different times and at different places may yield discordant results according to the route of comparison. In fact, a particular standard of length should apparently be used only at the time and place where it is, for in general, a vector will change its value on describing a circuit. The fundamental apparatus required for measurement is therefore no longer, as in the days before relativity, a unit standard, or indeed, a set of standards, one for each point of space, but a set containing a unit for each point of the fourfold manifold of space and time. Such a system of measures, comprising a fourfold series, is called a "gauge system" in Weyl's theory. In this analytical scheme, however, zero length is unique, and involves no specification of route. But Eddington, with his idea that it may be possible to introduce non-Maxwellian forces into the schema, further generalises this theory by allowing that zero length may not be unique.

In allowing the generalised idea of measurement of Weyl, and of course, still more in countenancing the suggestion of Eddington, we are abandoning a well-established belief in common sense; and indeed, this is the crux of the matter from the point of view of ordinary life. But this is, of course, not the first time that the theory of relativity has asked us to throw away the beliefs of everyday life. These theoretical developments—and, in fact, the whole of relativity theory—have attained so great a degree of complexity that they have far outstripped the powers of deduction possessed by naïve common sense; and this is so in spite of the fact that they, in common with all other branches of physics, started from ordinary common-sense data. The difficulties, from a common-sense point of view, of the theory of relativity, of which we unfortunately hear so much, are due in great measure to the fact that, owing to the extensive analytical development, the postulates from which it starts have no obvious connection with the physical facts which the theory is designed to correlate. Tensors, for example, involve quantities to which no simple physical significance can at present be attached. But even the concept of energy, which has long since taken its place as a physical idea, must at one stage of history have been a difficult idea to the natural philosopher previously limited to concepts such as force. The concept of *action*, as used in the quantum theory at the present time, is scarcely one which the physicist, left to himself, would readily employ, unless it is regarded as being invariably an angular momentum. The Lagrangian idea of *generalised co-ordinates* in dynamics is another case of the same kind. The concepts employed in relativity are at present remote from physical ideas in exactly the same way, though perhaps to a greater extent.

THE THEORY OF RELATIVITY AND COMMON SENSE.

In mathematical theories, not infrequently the logical links between the premises of the problem and the results deduced from them are so many in number that no connection can at first sight be seen between them. In fact, the greater the number of links the more valuable the theory becomes. The purely mathematical background of the theory of relativity consists largely of developments which belong to highly specialised domains; and it is not to be expected that common sense can foresee the results obtainable from specified assumptions which the data of common sense have been found to require. Indeed, we might point out that it is apparent from the mere fact that the tensor theory has been built up into an extensive branch of mathematics (which, of course, happened long before its applications were dreamed of) that the connection between the premises and the results is too complicated to be dealt with without the aid of a specially elaborated technique. It is therefore impolitic to advance common-sense criticisms of the various assumptions as to length which may provisionally be advanced in the theory of relativity with the definite object of effecting further comprehensive correlations of physical facts. For common sense, having provided the jumping-off ground, has a severely restricted part to play in the more technical analysis which the logical development of these assumptions requires; and it is at once the marvel and the allure of the science of our day that mathematics, which is but the child of common sense, has been able, owing to the masterly researches carried on by the pioneers of the nineteenth century, to transform the crude views of her parents into the triumph of modern physics.

Current Topics and Events.

The Rothamsted Experimental Station has taken over the Stackyard field, Woburn, which for many years was held by the Royal Agricultural Society of England, and proposes to continue the experiments on wheat and barley in close association with the work at Rothamsted. Although the Royal Agricultural Society thus gives up its experimental farm, it is gratifying to know that the Society does not intend to break its connection with scientific research; it has set up a Research Fund and a Committee to initiate or receive schemes for investigation, and it proposes to carry out its experiments on the farms of its members. In the first instance four problems will be studied:—(1) The value of ground mineral phosphates, more particularly in the improvement of pasture. (2) The use of various forms of lime on grass and tillage crops. (3) The use of wild white clover, wild red clover, bird's-foot trefoil, etc., in laying down land to grass. (4) The profitable utilisation of whey. We welcome this further evidence of the recognition now widely accorded by farmers to the necessity for further research work in agriculture, and we trust that fruitful means of carrying out such work will be found. There are certain difficulties which should be pointed out. Unless the programme of work and the actual experiments are closely supervised by scientifically trained men, there is great danger that the results may be incomplete, giving much less information than might otherwise be obtained. Without a carefully-drawn-up programme something vitally important is liable to be left undone, or some observation omitted, and in agricultural investigations lost opportunities rarely recur. Moreover, there is a real danger of overlapping; at the present moment there are already two separate bodies studying the effects of mineral phosphates on grassland; fortunately they have co-ordinated their efforts. Neither of these difficulties is insuperable and we have little doubt the Committee will be able to overcome them.

Scarcely any department of scientific research is of such general interest as that which concerns prehistoric man, his development during the Ice Age and the changes then taking place in the conformation of land and sea. Yet, with the exception of the Institute of Human Palæontology in Paris, which was generously endowed by Prince Albert of Monaco, there has been hitherto no special centre for the investigation of this deeply interesting and important period. A public institution for study of the Ice Age has now been established in Vienna in connection with the Natural History Museum of the Austrian Republic, and every effort will be made to investigate the phenomena of the Ice Age on a broad scientific basis. The geographical position of Vienna renders it well adapted for this purpose, since the land structures associated with the glaciation can be studied in the near vicinity and observed in their ancient relations to the environment of pre-historic man. Lower Austria has already furnished a rich store of ancient stone implements and weapons. The Vienna Institute is under the able leadership of Dr. J. Bayer, director of the anthropological and ethnographical collections. Dr. Bayer's papers, in which he demonstrates the existence of no more than two distinct periods of glacial conditions, may be said to have created a new basis for this field of research. Dr. Bayer is assisted by a distinguished group of colleagues, and it is hoped to extend the circle of workers to include those in other countries who are devoting themselves to research on this period. Any such are freely invited to enter into communication with Dr. Bayer at the Natural History Museum, Vienna, who will be pleased to give fuller information as to the present activities of the Institute.

The *Daily News* for March 3 contained an article of three columns by W. B. W. on the constitution of the atom according to the nuclear theory and the disintegration of the atoms of the lighter elements which has been effected recently by Sir E. Rutherford and Dr. Chadwick. The results of their work were recorded in the November issue of the *Philosophical Magazine*, and Sir E. Rutherford gave an account of them in his address to the Chemical Society a few days ago. We welcome the appearance of articles on scientific subjects in the daily press, as they furnish one of the best means of keeping the public acquainted with the interesting work which is being done. There is a tendency, however, in such articles to represent each development as a sensational one, and the public gets the impression that the foundations of science are overturned every month or two. It is not in the interests of science that such a false impression should be produced, and we see no reason why a sensational turn should be given to an article on a scientific subject while an archæological discovery is allowed to speak for itself. There is room in the daily press for a regular series of articles on scientific subjects to maintain the tradition established by Lord Rayleigh and Sir Ray Lankester a dozen years ago.

The British Non-Ferrous Metals Research Association has just issued its second annual report. During the past year the membership of the Association has increased very largely, the principal trade associations having joined it. The programme of research work which has been undertaken is very extensive and has been divided among various university and national laboratories and individual firms having the necessary equipment. The influence of impurities on copper, the polishing of metals, atmospheric corrosion and methods of joining metals, are among the subjects now being investigated, and considerable progress has been made in dealing with some of them. At the second annual meeting, held in Birmingham on March 3, and preceded by a luncheon, the progress of the Association was surveyed. Vice-Admiral Sir George Goodwin, Dr. Rosenhain, Sir Henry Fowler, and Sir Frank Heath were among the speakers, who emphasised the importance of co-operative research of this kind to the metal industry. The policy of the Association is not confined to the solution of imme-

diate works problems, but involves a thorough study of the fundamental properties of the principal non-ferrous metals and alloys. In the adoption of such a far-sighted policy it is certain that the Association has taken a wise step, since the more important advances in industrial progress are usually the result of research on fundamental problems rather than on the overcoming of minor difficulties.

AN explanatory statement on the Navy Estimates has been issued by the First Lord of the Admiralty as a White Paper (Cmd. 1603). In a detailed account of the reductions in the various votes which go to make up the estimates, Lord Lee announces that the expenditure on education and scientific services in the Navy is to be reduced by 122,000*l*. The Admiralty is of opinion that a more drastic reduction would be undesirable at a time when it is hoped that the Navy will make up in quality of *personnel* and superiority of technique for the lead that has been surrendered in respect of *matériel*. The importance, and the previous inadequacy, of scientific research was clearly demonstrated during the War, and the Admiralty is convinced that the measures which it has taken are not more than sufficient to maintain research and experiment on a sound though economical basis.

THE Summer-Time Bill was read for a second time in the House of Lords on March 9. The measure provides that summer-time shall begin on the night of the last Saturday in March (unless the next day be Easter Sunday), and come to an end on the first Saturday in October. This year, therefore, summer-time will come into force at 2 o'clock G.M.T. on the morning of Sunday, March 26, and will continue until 2 o'clock G.M.T. on the morning of October 8. The French Chamber of Deputies on March 9 voted against the adoption of summer-time, but afterwards accepted an amendment to introduce it this year on account of arrangements already made with Great Britain and Belgium. The Senate agreed on March 14 to adopt this course, but prefects are to have local option of following the old time.

PROF. M. PLANCK has been elected a foreign member of the Swedish Academy of Sciences, Stockholm.

SIR ERNEST RUTHERFORD, Cavendish professor of experimental physics in the University of Cambridge, has accepted the nomination of the council of the British Association to be president for the annual meeting to be held at Liverpool next year.

ON Tuesday next, March 28, at three o'clock, Dr. J. W. Evans will begin a course of two lectures at the Royal Institution on "Earth Movements." The Friday evening discourse on April 7 will be delivered by Sir Ernest Rutherford on "The Evolution of the Elements."

WE record with deep regret the death on March 19, at sixty-one years of age, of Dr. G. B. Mathews, formerly professor of mathematics, University College of North Wales, and for many years a much esteemed contributor of reviews and articles on mathematical subjects to our columns.

DR. O. STAPF, who has been keeper of the Herbarium and Library at the Royal Botanic Gardens, Kew, since 1908, retired on February 28, having reached the age limit. He is succeeded as keeper by Mr. A. D. Cotton, formerly a member of the Herbarium staff and lately mycologist to the Ministry of Agriculture and Fisheries.

THE following were elected fellows of the Royal Society of Edinburgh at the Ordinary Meeting on March 6:—Mr. C. L. Abernethy, Prof. G. Barger, Sir Dugald Clerk, Dr. F. A. E. Crew, Dr. W. O. Greenwood, Mr. W. A. Guthrie, Prof. R. K. Hannay, Prof. E. Hindle, Dr. C. F. Juritz, Prof. J. C. Meakins, Mr. M. Macgregor, Dr. Bijali Behari Sarkar, Prof. H. W. Turnbull, Dr. J. Walker, Mr. J. Wilson, Mr. J. M. Wordie.

THE Anglo-Swedish Society has awarded its travelling scholarships for this year to Miss Joan Evans, librarian at St. Hugh's College, Oxford, to enable her to study the collections of early gold work in the Swedish museums; and to Mr. W. N. Edwards, of the Geological Department of the British Museum, to enable him to study the fossil plants in the museums of Stockholm, Upsala, and Lund.

A COMMITTEE has been appointed by the Minister of Health to advise on the preliminary steps to be taken in regard to the site and planning of the School of Hygiene, in London, towards the building and equipment of which the Rockefeller Foundation recently promised a gift of two million dollars. The members of the Committee are:—Sir Arthur Robinson (chairman), Sir Frank Baines, Dr. H. H. Dale, Sir Walter Fletcher, Sir William Leishman, Sir George Newman, Sir Cooper Perry, Sir Herbert J. Read, and Dr. H. Meredith Richards (secretary).

AT the annual general meeting of the Ray Society on March 9 the following officers were re-elected:—*President*, Prof. W. C. McIntosh; *Treasurer*, Sir Sidney F. Harmer; *Secretary*, Dr. W. T. Calman. Dr. B. Daydon Jackson was elected a vice-president. and Mr. E. T. Browne, Prof. E. B. Poulton, and Dr. A. Smith Woodward were elected new members of council. In the report of the council regret was expressed that it had not yet been possible to issue the first part of the fourth volume of Prof. McIntosh's "British Marine Annelids," due to subscribers for 1920, owing to delay in the execution of the coloured plates. It is hoped to publish it in the near future, and the second part of the volume, which will complete the work, will be taken in hand at once and will form the issue to subscribers for 1921.

AT the meeting of the Royal Geographical Society on March 20, the president announced that H.M. the King has approved the award of the Royal Medals as follows:—*The Founder's Medal* to Lieut.-Colonel C. K. Howard-Bury for his distinguished services in command of the Mount Everest Expedition of 1921; *The Patron's Medal* to Mr. Ernest de K. Leffingwell for his Surveys and investigations on the coast of northern Alaska. The Council has awarded *The Victoria Medal* to Mr. J. F. Baddeley for his great work on the Historical Geography of Central Asia; *The Murchison Grant* to Mr. Charles Camsell

for his Explorations and Surveys in northern Canada; *The Back Grant* to Khan Bahadur Sher Jang for his Surveys on the Indian Frontier and in adjacent countries; *The Cuthbert Peek Grant* to Mr. F. H. Melland for his Explorations in Northern Rhodesia; and *The Gill Memorial* to Mr. A. A. R. Boyce for his triangulations in the Sudan.

AT the Annual General Meeting of the Optical Society, held on February 9, the following officers and members of council were elected:—*President*: Sir Frank Dyson. *Vice-Presidents*: Prof. F. J. Cheshire, Mr. T. Smith, Mr. R. S. Whipple. *Treasurer*: Maj. E. O. Henrici. *Secretaries*: (*a*) *Business Secretary*—Prof. Alan Pollard, Imperial College, South Kensington. (*b*) *Papers Secretary*—F. F. S. Bryson, Glass Research Association, 50 Bedford Square, W.C.1. *Librarian*: Mr. J. H. Sutcliffe. *Editor of Transactions*: Dr. J. S. Anderson. *Council*: Dr. J. S. Anderson, Instr.-Comdr. T. Y. Baker, Mr. L. Booth, Mr. R. W. Cheshire, Dr. R. S. Clay, Dr. J. W. French, Mr. W. Gamble, Mrs. C. H. Griffiths, Mr. J. Guild, Mr. L. C. Martin, Dr. R. Mullineux Walmsley, Prof. A. W. Porter, Mr. J. Rheinberg, Mr. A. Whitwell. Prof. A. A. Michelson, of the University of Chicago, and Dr. M. von Rohr, of Messrs. Carl Zeiss, Jena, were elected Honorary Fellows of the Society.

THE Annual Report of the Delegates for Forestry at Oxford shows a large number of students in this subject during 1921, no less than 52 (including 2 ladies) having been awarded the Diploma in Forestry. Of these 45 obtained Government appointments. Practical work was carried out by the students in the Crown woods of Dean, Tintern, and High Meadow and in Bagley wood near Oxford. The list of published papers by members of the staff shows research mainly in insect and fungus pests.

THE annual report of Livingstone College for the year 1920–21 has recently been issued. The College is doing excellent work in training missionaries in the elements of medicine, and 36 students entered for varying periods during the session. There is now an accumulated deficit of 1021*l*. on the working of the College, and subscriptions are earnestly asked for, There is great need for bursaries of about 50*l*., which could be offered to missionary societies or to suitable candidates to enable students to enter for the full course of the College.

IN the January number of *The Fight against Disease*, published by the Research Defence Society, an account is given of the Nottingham outbreak of smallpox down to November 21 last. The number of cases was 81, none of which proved fatal. Of these, 65 occurred in unvaccinated persons, and in none of the others had vaccination been performed within thirty-three years of the attack. All members of the Hospital and Health Department staffs in contact with the smallpox cases—some 120-130 in number—were recently vaccinated, and no member of these staffs contracted the disease.

MESSRS. BURROUGHS WELLCOME AND CO., of Snow Hill Buildings, E.C.1, have just issued another booklet, which may be had free on application. "The Right Way in Photography" gives instructions that reduce the process of taking photographs to a mere matter of routine. The booklet will prove of interest and use to those who do not need elementary instruction by reason of the various tables it contains, showing the times of development required at various temperatures, using various tanks, and various strengths of solutions; and a very long list of plates, classified according to the multiplier of the time indicated that is necessary for each.

THE *Journal des Débats* states that during a visit to the National Porcelain Factory at Sèvres the President of the Republic and Mme. Millerand were shown the operation of an experimental oil-fired porcelain kiln. Hitherto the kilns have been fired by wood (oak for the small and birch for the large furnaces), but it is pointed out that the Copenhagen factory has, for some time past, been using oil-fuel, which affords better control and necessitates only one man per kiln instead of two. The results of the experiments at Sèvres have been fully satisfactory, and although fuel oil is costly in France at present, it is thought that its application to pottery and porcelain firing may sooner or later revolutionise the ceramic industry.

THE Spanish NATURE (*Iberica*) continues to make rapid strides, and the recent double number (January 21-28) is a remarkable production in every way, many of the advertisements being excellently produced in colours. Among the contents may be mentioned a full description, well illustrated, of the new commercial university at Deusto, which is laid out and equipped on modern lines. Another interesting description is that of the largest quicksilver minefield in the world at Almadén, in the province of Ciudad Real, which comprises to-day twelve separate mines having an annual output of some 20,000 bottles of mercury of 11·5 kilos each. There are notes on the New Metropolitan Railway in Madrid; an interesting article, illustrated in colours, on geometrical anaglyphs and stereoscopic vision; a brief historical account of developments in locomotive design; some notes on the progress of railway electrification in Italy; and the usual notes from foreign sources.

WE have received a circular announcing the publication in Italy of an Encyclopaedia of Science and Arts. The work, which will be entirely new and contain twice the number of articles of the present edition of the "Encyclopaedia Britannica," is to be under the direction of Prof. Giorgio Giuseppe Ravasini da Buie d'Istria, and will be prepared in collaboration with the foremost scientific authorities in Italy. Articles and information from private individuals will be welcomed and paid for, according to their value and number, in money or in one or more subscriptions to the complete work. The encyclopaedia will be copiously illustrated by ordinary and coloured plates, maps, plans, etc. The publication of the work is being undertaken by the publishing house of the Accademia "Scienze ed Arte," and all inquiries regarding subscriptions or contributions should be addressed to Accademia "Scienze ed Arte," Sezione Enciclopedia, Via Ugo Foscolo 2, Trieste (Italy).

Our Astronomical Column.

THE APPROACHING OPPOSITION OF MARS.—Mars will be closer to the earth next June than it has been since 1909; the opposition of 1924 will, however, be still closer, the distance being then almost the absolute minimum. The high south declination next June of 26°, making its meridian altitude at Greenwich only 12°, will prevent any useful work from being done in this country. The nearest approach to the earth, 0·45 astronomical units, is on June 18; a week later the autumnal equinox of the northern hemisphere will occur, so that both polar caps should be visible. The earth will remain to the north of the Martian equator till mid-September.

PLANETARY OBSERVATIONS AT SÉTIF.—M. Jarry-Desloges established an Observatory at Sétif, N. Africa, specially for planetary and lunar observations, and he has lately published a large illustrated volume containing studies of the moon and all the planets. Mercury was found a fairly easy object by day, the spots being nearly as well-defined as those of Mars. The results confirm those of Schiaparelli and Lowell, making the period of rotation 88 days, equal to that of revolution. Other observers have concluded that the low albedo, and the absence of an external ring of light when the planet is entering on the sun in transit, negative the idea of an appreciable atmosphere; this volume, however, supports the presence of occasional mist or cloud veiling some of the markings and altering their aspect. It is pointed out that the light and heat received from the sun at perihelion and aphelion are in the ratio of 9 to 4, which would make much difference in the precipitation or dissipation of cloud. Most of the markings are broad, curved, dusky streaks, some 60° in length; there are a few larger spots. The colour of the disc was generally rosy.

Drawings of Uranus show markings not unlike those of Saturn; there is a bright equatorial belt, and fairly bright belts in each temperate zone, with darker regions between them and round the poles. The markings are much inclined and curved, but exact measures are not given. It was noted that the direction of the belts changed during the night, showing that they cannot be quite parallel to the equator. Dark belts were also seen on Neptune, making in 1914 an angle of some 40° with the east-west line, and slightly curved. Neptune's satellite Triton was generally easier to see than Mimas; two fainter stars were seen on February 15, 1914, between Triton and Neptune.

There are also interesting drawings of Saturn, showing notches in the outline of the Cassini division, and in that of the crêpe ring. The markings seen on Venus were so vague and difficult that no deduction was made of the rotation period.

STARS OF CLASS A IN THE SOLAR CLUSTER.—Both Sir J. Herschel and Dr. Gould noticed a zone of bright stars, the medial line of which makes a small angle with the Milky Way. Later on, the local cluster of B stars studied by Prof. Charlier was found to mark out nearly the same great circle. Dr. Harlow Shapley and Miss Annie J. Cannon, in Harvard Circular No. 229, describe the distribution of the stars of spectral type B8, B9, A0, A2, A3, of magnitude 6·5 or brighter. The stars, 2450 in number, are plotted in galactic co-ordinates on an equal-area projection. The median galactic latitudes of the stars in each 10° of longitude are then found and marked with crosses. The resulting smoothed curve shows maxima and minima as follows: long. 50°, lat. +5°; long. 195°, lat. −6°, long. 300°, lat. +7°; long. 335°, lat. −4°. These results are considered to confirm the existence of the local cluster, but also to show the presence of some disturbing factor, possibly a separate cluster about the region of Corona Austrina. It is intended to pursue the investigation with stars of "later" spectral types, for which spectroscopic parallaxes can be found.

THE PERTH SECTION OF THE ASTROGRAPHIC CATALOGUE.—The publication of Zone −35° of this catalogue by Mr. Curlewis was noticed in this column a few weeks ago. Zone −33° has followed it after a very short interval, the arrangement being in all respects similar. It appears in 4 parts, each containing 6 hours of R.A.; they contain respectively 7393, 25,882, 21,163, and 16,365 stars. The variation in star-density with galactic latitude is again very striking; it will be remembered that the south galactic pole is in Decl. −29°, so that these zones embrace practically all galactic latitudes. The ratios of the numbers of stars in each volume to those given in the same areas in the Cape Durchmusterung are 3·5, 5·7, 5·7, 4·6 respectively. Actually the extreme ratios are 2 in poor fields near the galactic pole and 8 in rich galactic fields.

The places of the reference stars have been taken from the recent Perth Catalogue; the tables for reduction from rectangular co-ordinates are in the same form as those in the Oxford Astrographic Catalogue.

THE LIGHT-CURVE OF NOVA CYGNI, 1920.—An exhaustive discussion both of the light-curve and of the colour variation of this Nova is given in Publications of Urania Observatory, Copenhagen, 2nd Series, No. 3. The Nova was of special interest from its comparatively slow rise to maximum and its early visual detection, which enabled observations to be made on the up-slope of the curve: two photographs taken before discovery, at Kvistaber, by Mr. Tamm, and at Harvard, fully confirm the leisurely nature of the increase of light. The apex of the curve, at mag. 1·8, is very sharp. The fall of light was at first very rapid, amounting to 2½ mags. in ten days; it then became slower but still uniform for 3 months. Here it began to be oscillatory; after another 3 months the oscillations grew larger and the diminution of light slower; in the year ending 1921 Sept. the mean magnitude fell from about 8·6 to 9·7.

The colour determinations are much less consistent than those of magnitude, but they suffice to indicate that at discovery the colour was less than 2, while three months later it rose to 6 or 7, on a scale extending from 0 (white) to 10 (red). The colour at maximum was yellow. A table of photographic magnitudes for the first six months is also included in this publication. This indicates a fall of light from magnitude 2·12 (at maximum) to magnitude 10; a comparison of this table with that giving the visual magnitudes fails to indicate the rapid increase in redness after maximum which the observers noted.

SLIDES OF PHOTOGRAPHS TAKEN AT YERKES OBSERVATORY.—The beauty of the slides taken with the 40-inch refractor at Yerkes Observatory is well known, and a selected list of a hundred slides is now being offered for sale. The price asked is 62½ dollars in addition to carriage; 75 cents is charged for single slides, and double this amount for coloured slides.

Research Items.

THE BULL ACROBATS AT KNOSSUS.—In the Journal of Hellenic Studies (vol. xli. part 2) Sir Arthur Evans describes a remarkable bronze group from Knossus in Crete, representing an acrobat jumping over a galloping bull in the arena. The high action and skilful modelling of this animal are altogether unique among the relics of Minoan metallurgic craft, and for vigour and beauty this far exceeds two representations of such feats discovered by Schliemann and others. The full stretch of the bull's legs conforms to what is known as the "flying gallop" scheme, and the small figure of the acrobat, apart from the conventional attenuation of the waist, is finely executed, and even his features, though abnormally diminutive and incompletely brought out by the casting, with the sinewy development of form, due to athletic training, are well indicated. In other examples of feats of this kind the performer is usually a girl, but there can be no doubt that this figure is a male. In a representation of the same class on the bull *rhyton* it is clear that at the epoch to which it belongs, that is, about 2000 B.C., the long-horned Urus breed of cattle had been already introduced into Crete. The earlier indigenous variety, a form of shorthorn, *Bos Creticus* of Boyd Dawkins, was not well adapted for such a form of sport.

THE PALÆOLITHIC AGE IN INDIA.—The discovery of stone implements in India began with an implement found by Mr. Le Mesurier in 1861, and since that time many specimens have been found. But only two cases are known in India where stone implements have been found associated with the remains of extinct animals, in the Nerbudda and Godavari valleys, and further evidence of their occurrence in strata, the date of which can be established, is much to be desired. In the March issue of *Man* Mr. T. H. Vines reports the discovery of flint workshops in hills overhanging the North Indus valley. These consist of cores and broken chips, with a yellowish-brown fabrication and lustre. In the ravines of these hills flint knives and other tools of a white or whitish colour are found in considerable numbers. Mr. Vines suggests that the strata in which these implements are found correspond with the area in Egypt where implements of the same type have been discovered by Prof. Seligman (Journal Royal Anthropological Institute, vol. li. p. 115). The area to which Mr. Vines refers well deserves examination, as its geological character may form the basis of fixing an approximate age for manufacture of these implements.

MAN IN THE PACIFIC.—At the meeting of the British Association held in Australia in 1914 the desirability of fuller knowledge of the Pacific was advocated. In response to this appeal the Legislature of Hawaii appropriated funds to be used by the Pan-Pacific Union in defraying the cost of a Pan-Pacific Commercial and Educational Congress to be held at Honolulu in 1920. The Bernice P. Bishop Museum has now issued, as No. 7, Part I., of its publications, a full report of the Proceedings of the Congress, which are of peculiar interest. The papers now published are devoted to the question of Race Relations. In a valuable paper on "Man in the Pacific," Dr. Clark Wissler remarked on the need for such investigations as "the old Polynesian is passing the last mile-post of his career." "First, we need a geological survey of the several island groups; for the backbone of man's chronology is geological chronology. Further, we need data upon the fauna and flora of the respective islands. It is the realisation of this inter-relation of problems that underlies the conception of this congress and is its only excuse for being. You tell us the history—a relative chronology—of such plants as taro, bread-fruit, the paper mulberry, etc., and the story of such mammals as the pig and dog, and of the chicken, in the islands of the Pacific, and we will soon fill in the gaps in the chronological scheme for the Polynesians."

THE AMERICAN INDIANS' KNOWLEDGE OF THE MASTODON.—In *Natural History*, the Journal of the American Museum of Natural History (vol. xxi. No. 6), Mr. J. L. B. Taylor, under the heading: "Did the Indian know the Mastodon?" describes a bone bearing an incised elephant-like figure, found in the Jacobs Cavern, Ozark Country, near Pineville, Missouri. Dr. Clark Wissler, who has examined this bone, regards the work as what might have been expected from the hand of an American native; three attempts to represent living forms, apparently by the same artist, are identified—"Two have the distinctive lines of elk and deer, while the lines of the third characterise elephant kind, and this favours the interpretation that an elephant, mastodon, or mammoth was intended. At once the objection will be raised that the bone is recent. Though the mastodon and the mammoth are characteristic of Pleistocene time, it is not known when they became extinct: for all that is known to the contrary these great mammals may have held out within 3000 years ago. . . . No one in authority seems now prepared to deny that man was in America 3000 years ago." Dr. Wissler regards this discovery in Jacobs Cavern as of great importance; "it is to be hoped that at last we are on the trail of early man in America."

BEHAVIOUR OF STOMATA.—In a significant paper on the behaviour of stomata (Carnegie Institution of Washington, Publ. No. 314) Mr. J. V. G. Loftfield has made important additions to our knowledge of the action of stomata in relation to the environmental and physiological conditions of the plant. He used the method of fixing strips of the epidermis in alcohol, supplemented by direct microscopic observation of the living, attached leaf. Many of the observations were continued every hour throughout the day and night, microphotographs showing the condition of the stomata on the upper and lower epidermis of leaves being ingeniously arranged in circles for comparison with the corresponding continuous circular records of light, temperature and humidity. Many plants were studied under different climatic conditions, and it was found that while illumination affects the action of stomata, as has long been known, yet weather conditions also control the size of the openings, and with varying water supply the stomata may change their behaviour from day to day. Some of the movements were quite rapid, from fully open to closed in less than an hour. Low morning temperatures caused the stomata to open very gradually, and even moonlight affected the size of aperture. The great majority of the stomata on a leaf behaved alike, but about 2 per cent. were functionless and 3 per cent. superfunctional, opening to twice the normal maximum. The plants studied fell into three groups. In cereals the stomata are very sensitive and never open at night. In another group, as conditions become less favourable the stomata open at night and close for a time about midday. In the potato and other plants the stomata are normally open at night and close only under conditions of high evaporation or low water-content. Light induces the opening of stomata by causing the conversion of starch in the guard-cells into sugar and so increasing their osmotic pressure. This work

shows that stomata are regulatory in their action, a fact on which earlier investigations had thrown some doubt. It indicates that there are considerable fluctuations in the water-content of a normal leaf, and that the regulation of water-loss by the stomata is very effective when they are nearly closed.

Silk Weavers and their Output.—In Report No. 17 of the Industrial Fatigue Research Board, Mr. P. M. Elton analyses the differences in the output of individual silk weavers. Silk weaving is a highly skilled occupation, and it takes at least two years to teach a girl to weave quickly and well. Hence it is very important that unsuitable girls should not waste their own time, and that of their employers, in undergoing training. Training has often been faulty in the past, and in consequence bad methods of work are acquired which are never eradicated. So important is the human factor for success in silk-weaving that the quickest operatives consistently produce about twice as great an output as the slowest. Mr. Elton analyses the causes of these wide variations in detail, and his report should be of great value to those engaged in teaching young weavers. A weaver has to have good eyesight, be dexterous with both hands (for in weaving both hands are simultaneously employed on very different operations), and have a delicate sense of touch. Mr. Elton has not endeavoured to determine the most suitable tests for would-be apprentices to the weaving industry, but there should be no difficulty in the choice of some of the necessary tests. A thoroughly adequate selection can only be made gradually, after much experiment, but few more fertile fields for the application of the principles of "vocational selection" [can offer themselves than that of weaving.

Electrical Precipitation in Industry.—In the Journal of the Society of Chemical Industry for February 15, Dr. H. J. Bush gives an account of the industrial applications of electrical precipitation. In 1884–86 Sir Oliver Lodge carried out experiments on the electrical deposition of fog and smoke, and patents were taken out in England and other countries during those years. In 1884 Dr. Karl Moeller, in Germany, obtained an independent patent. In 1906, Dr. F. G. Cottrell, Director of the United States Bureau of Mines, then professor of physical chemistry in the University of California, repeated Lodge's experiments in connection with the removal of acid mists, and in his hands the process has been largely developed. During the war a very large Cottrell plant was in operation at the Queen's Ferry works, and an installation was designed by the Lodge Fume Co. for cleaning blast-furnace gases. Dr. Bush gives an account of these and other plants. The principle is very simple. An insulated wire hangs inside a metal tube, both being connected with a high voltage transformer, or special electrodes are hung between metal plates. The fume passes through the apparatus, and the electric discharge brings about its precipitation. The mechanism of the process appears to be somewhat obscure, and the account given by Dr. Bush is very empirical. Further scientific work will probably throw light on this interesting process. Electrical precipitation has a large field of possible applications.

Separation of Isotopes of Mercury.—In the January number of the Journal of the American Chemical Society, Prof. W. D. Harkins and R. S. Mulliken describe the experimental separation of mercury into isotopic fractions by evaporation in a vacuum. A difference in density of 133 parts in a million was obtained. A theoretical discussion of the resolution of isotopic mixtures by diffusion and similar processes is given, and equations are obtained showing the rate of separation to be expected in such processes. This work supplements previous results by other workers given in Nature, vol. cvi. p. 144; vol. cviii. p. 209.

Ammonia Oxidation.—During the war the oxidation of ammonia was studied in England with a view to its application in the State factory for the fixation of nitrogen. Although the other parts of the chain of operations leading from atmospheric nitrogen to nitric acid never materialised, the process of ammonia oxidation was brought to the stage of technical application, and was taken up by different firms in connection with the supply of oxides of nitrogen to sulphuric acid chamber plants. In the Journal of the Society of Chemical Industry for February 28, Messrs. C. S. Imison and W. Russell, of the United Alkali Company, give a very interesting and detailed account of the improved process now in operation. They remark that, so far as their experience goes, there is little difference in cost between this and the old retort processes for making strong nitric acid with nitre and ammonia at present prices, but if the published estimates for the cost of synthetic ammonia are realised in this country, the balance will turn strongly in favour of the oxidation process. They also point out that the oxidation process is an integral part of the process for the fixation of atmospheric nitrogen, which, in conjunction with a fixation process for ammonia, would render this country independent of overseas supplies of nitre in the event of another war. It seems strange that, among so much legislation for "key industries," the absolutely vital problem of nitrogen fixation has never been mentioned.

Radium Mining.—In a circular issued by the Colorado School of Mines, entitled "A World Storehouse of Rare Metals, Radium, Uranium and Vanadium, the Paradox Field of South-western Colorado," interesting information is given of the present conditions prevailing in what is undoubtedly the richest radium region of the world. The ore mined is carnotite, a potassium uranyl vanadate of the composition $K_2O,2UO_3,V_2O_5,3H_2O$, occurring in sandstone in the San Miguel, Dolores, Mesa, and Montrose counties of S.W. Colorado. The ore, as mined, contains usually from 1·4 to 1·8 per cent. of uranium oxide, averaging some 4 milligrams of radium to the ton and 4 or 5 per cent. of vanadium oxide. Of a total of 52,000 tons produced in the U.S.A., Colorado has produced 48,700 tons, of which 38,000 tons were mined by one company, the Standard Chemical Co. of Pittsburgh. Smaller quantities have been produced also in Wyoming and Utah. The ore is prospected for by diamond drilling to a depth of some 40 feet and mined by inclined shafts and gravity tunnels. The deposits occur in sedimentary rocks, and so far are confined practically to what is known as the M'Elmo formation. Though easily recognised as outcrops, the deposits of carnotite are exceedingly variable and obey no law of deposition. They are often associated with fossil wood as "logs," in which the mineral has replaced the trunks of trees embedded in the rocks. It is concentrated *in situ*, if of less than 2 per cent. U_3O_8 content, and furnishes not only the largest present source of radium but also an important source of the vanadium, now so largely employed in the manufacture of special steels. The Colorado School of Mines maintains a special well-equipped radioactivity laboratory for the estimation and evaluation of these ores.

Growth and Sex-Factors of Racial Character.

AT a meeting of the Royal Anthropological Institute held on February 28, Dr. W. H. R. Rivers, president, in the chair, Miss R. M. Fleming read a paper on "Growth and Sex-Factors in Racial Analysis." Her results were based on a large number of measurements made, for the most part, in Wales, the measurements in the case of the children having been repeated at regular intervals.

Miss Fleming said periodic re-measurement of children during growth shows that—

1. Boys and girls have different growth cycles as regards features used in racial analysis;
2. Head breadth commonly increases more than head length, so the cephalic index usually rises during growth. Cephalic index of girls rises most quickly between the third and eighth years, while in boys it does so especially after the tenth year. Changes of one unit in one year were general, and larger changes frequent;
3. The frequent darkening of hair and eye seen in both sexes shows the same difference of period, and also confirms the results of Pryor's work on ossification of wrist bones;
4. There are clear correlations between facts of physical growth and mental development, and these correlations should influence educational methods.

British women show more development of pigment, brachycephaly, and prognathism than do men. Sixty per cent. of any normal sample of men have cephalic index 75-79; nearly the same proportion of women have indexes 77-81. Men outnumber women under 75 and women enormously outnumber men over 84. Men have the glabella stronger and women the occiput larger in most cases, but this does not account for the difference, which is one of growth.

Among the types noted are the following:

a. Dark-haired, dark-eyed women, head length 181-193, head breadth 143-154, cephalic index 77-81, calvarium rather low, prognathism slight or absent, forehead usually full, occipital prominence marked and low.

About 50 per cent. of the sample of women studied possessed most of these characters, and they were very marked among the Welsh people. This group corresponds with Fleure's group of men of indexes 75-79, dark colouring, but the women show greater heterogeneity;

b. Dark-haired, dark-eyed women, head length 187-199, head breadth 137-148, cephalic index 76 or less. Bony development more marked and head height greater than in "*a*," forehead more often receding, prognathism often marked. A remote hill country pedigree is common for this type, and one often finds flattened nostrils, deep-set eyes, hair low on the forehead. A few are darker in youth than later on. Intellectual distinction is frequent.

c. Light-haired, light-eyed women, head length 180-192, head breadth 145-153, but measurements a little lower in general than in "*a*" and "*b*." Prognathism absent or very slight, bizygomatic breadth small, face long, calvarium finely arched, forehead often retreats, bones strong, stature averages 3 inches more than in "*a*" and "*b*." Type less frequent than "*a*" and "*b*" among purely Welsh peoples.

d. Fair longheads, very narrow, breadth about 132-137, low foreheads, slight build, low vitality.

It is not suggested that this group has any historical or racial significance. The fair and dark broadheads have not yet been examined in sufficient numbers to warrant discussion, especially as the analysis of male broadheads has not yet proceeded very far.

A discussion followed the reading of the paper, in the course of which Prof. Parsons pointed out that Miss Fleming's work corroborated the results which he himself had obtained both as regards the conclusion that the breadth of head of women was greater than that of men in the corresponding series, and that women were darker. Prof. Fleure said that Miss Fleming's work represented a real advance in the attempt to provide a sure foundation for physical anthropology, while it showed that the conclusions of Prof. Boas as to the change in head form of immigrants in the United States were unsound. Several speakers emphasised the importance of Miss Fleming's results for the educationist in connection with the classification and grading of children of both sexes.

Mortality Tables.

THE Privy Council Medical Research Council has published as the sixtieth of its Special Report Series a valuable memoir by Dr. Brownlee, the director of statistics of the council, on the use of death-rates as a measure of hygienic conditions (H.M. Stationery Office, 1922, 80 pp., 3s. net). Some of the methods employed for that purpose are likened by Dr. Brownlee to those of the tailors of Laputa. He divides the subject into two parts: (1) death-rates in general and (2) mathematical treatment, and illustrates it by 30 tables and 16 diagrams. On special points he has had recourse to Sir Alfred Watson, whose great experience in the construction of mortality tables must have been valuable.

The crude death-rate on a large population requires adjustment and correction. When applied to sections of the population, as to those dwelling in certain districts or those engaged in specified occupations, the liability to error is greatly increased. The method by which these are corrected is called "standardising."

For the purpose of life-tables the death-rate is taken to signify the ratio of the number of deaths of persons above any defined age, to the number living above that age, in a stationary population. They show some disadvantage in using standardised death-rates. So far back as 1875 the late Dr. Wm. Farr was sensible of this difficulty, and devised a method for meeting it, which Dr. Brownlee considers to present great advantages. Prof. Karl Pearson held that causes of death might be specially grouped to correspond with periods of life. Dr. Brownlee gives a re-drawing of Prof. Pearson's diagram (Trans. Roy. Soc., 1894) representing the curves for infantile mortality and the mortality of childhood, youth, middle age, and old age respectively.

The tables of Dr. Farr, based on returns from 1861 to 1870, provide information as to causes of death for selected districts according to sex and age. Later tables calculated by Mr. George King, the eminent actuary, show that the same conditions still hold. Dr. Brownlee supplies a table giving a summary of observations in various districts from 1838 to 1912, and comparing the standardised death-rates with the life-table rates for each observation. Though a life-table death-rate is the criterion of ultimate

importance, he arrives at the conclusion that there is a direct relation between it and a standardised death-rate. This is confirmed by some calculations made by Mr. Finch. Applying the death-rates at each quinquennial period of age to a standard population adjusted so as to be in arithmetical progression, for which purpose the mean population for the decade 1891–1900 was adopted, the errors appeared to be remarkably small.

Dr. Farr held that density of population and death-rate were closely connected. The difficulty has arisen in applying the two to London, which possesses a greater absolute healthiness than its density would suggest. May we not infer that this is partly due to good management and sanitary conditions?

It is less easy to get trustworthy generalisations where the numbers are small. Dr. Brownlee supplies a valuable series of tables of the numbers living and the expectation of life in selected healthy and unhealthy districts for use in calculating the death-rate from various diseases. He infers from them that persons who died at the age of fifty-one years in the average environment might have had a life of seven years longer in the mean had they lived in the country.

Proceeding to the consideration of the effect of particular diseases, Dr. Brownlee takes (1) Phthisis. The age at which phthisis causes death is shown to vary greatly in different districts. (2) Sarcoma and cancer. Here for an equal number of deaths the age at death is shown to be later where the conditions are healthier. (3) Valvular disease of the heart. This seems to behave in much the same way. (4) Diabetes. Here, whether a person lives in a rural district or in a county borough, the commonest age at death is the same. (5) Nephritis. This is much less prevalent in rural than in city districts. (6) Pneumonia. Deaths from this are least in rural districts. Care has to be taken in dealing with the three elements of the problem, age, environment, and disease.

In pt. 2, relating to the mathematical treatment of the subject, Dr. Brownlee seeks to give directions for calculating life-table data by short and easy methods. Those desirous of making inquiry into health conditions will, however, have to bear in mind the many pitfalls that they may meet in so delicate an investigation. Dr. Brownlee's authoritative and suggestive report will enable them to avoid the danger of hasty conclusions.

Population Maps.

THE possibilities of the quantitative representation of geographical data as regards population distribution are discussed in some detail by the originator of a new method, Mr. S. de Geer, in the *Geographical Review* for January. Mr. de Geer has already applied the method in the recently published atlas of the distribution of population in Sweden. In the ordinary map the position and size of cities and smaller centres are shown by dots. A further development is to show relative density by shading or colour-tints of varying depths. The chief defect of such maps is that, as a rule, they show only the average over large areas such as counties or parishes.

The dot method of Mr. de Geer offers the possibility of combining a clear representation of situation and a mass of population within wide limits. The dot represents a unit of population of fixed value; the larger the scale of the map the smaller the unit. On a scale of 1 : 100,000 a dot might represent ten persons; on one of 1 : 80,000,000 perhaps a million persons. The unit-dots are considered as small spheres, and should be shaded as such, but this involves expense and difficulties in printing; they are therefore drawn solid black. Small towns are shown by groups of dots arranged in squares, rectangles, or other figures corresponding roughly with the extent of the settlement. Such regular arrangements at once differentiate urban centres from rural communities. Large centres cannot well be shown by dot-nets because of the space required. Urban populations about a certain number, varying with the dot-unit chosen, are shown by large spheres the volume of which is proportional to the unit-dot and decided by the population of the centre. Thus in the Swedish map the unit-dot, representing 100 persons, has a radius of 0·57 mm., and the sphere representing Stockholm (371,000 inhabitants) has a radius of 8·9 mm. These large spheres are shaded to give a spherical appearance. As the quantitative value of the larger sphere is not readily estimated, it is expressed in units printed on or beside it.

Much geographical judgment must be used in the placing of the dots, especially in rural districts. The population of isolated farms and small hamlets has to be gathered into groups of 100 if that is the unit chosen. The dot is placed either at that place with more than half this number of inhabitants or, if there is no such place, near the centre of gravity of the group. Due regard must also be had to the density of neighbouring groups, particularly near administrative boundaries. The map is further improved by tints of colour distributed to show relative density of population. Mr. de Geer rightly claims that such a population map has many practical applications in questions of the readjustment of administrative boundaries, of the establishment of public institutions, of lines of communications, of the location of educational facilities, of the stationing of officials, and in other directions.

The International Fishery Investigations.[1]

THE International Council for the Exploration of the Sea met at Copenhagen in July last, and the official account of the proceedings is now available. An unofficial report, with some criticisms, has also been published by M. Ed. le Danois. At this meeting Belgium, Denmark, Finland, France, Great Britain, Holland, Norway, and Sweden were represented, and negotiations are in progress for the inclusion of Spain, Portugal, Esthonia, and Lettonia. The Governments of Canada, Newfoundland, and the United States have meanwhile adopted a joint scheme of oceanographical investigations, and contemplate "establishing contact" with the European organisation.

The official report summarises the proceedings of the council, the sections, and committees; the latter relate to investigations on the herring, cod and haddock, plankton, hydrography, limnology, statistics, the Atlantic slope, the Baltic, and the plaice. Programmes of the researches contemplated in each of these subjects are given, and there are indications of the share taken by each country and of the limited progress that has been made. So far little has been published. M. le Danois's unofficial report is, in part,

[1] Rapports et Procès-Verbaux des Réunions: Conseil International, Exploration de la Mer, vol. 27, Copenhague, December 1921.
Notes et Mémoires, No. 11, Office scientifique et technique des Pêches Maritimes, Paris, December 1921.

critical. He finds the methods that have been adopted by the council much too theoretical and too purely scientific. He hopes much from the British delegates, who also wish to see the work directed more strictly towards the treatment of practical problems. These reflections are very interesting.

The first practical outcome of the fishery investigations is the report of the Plaice Committee. For twenty years the question of the depletion of the plaice-stock of the North Sea has been under investigation, but the study of the post-war conditions has now hastened consideration of all the evidence. The workers associated with the International Council hold that a progressive impoverishment was in progress up to the year 1914, and that the great restrictions on fishing due to the war arrested this decline and restored the plaice population of the North Sea. They ask that restrictions on fishing should be imposed so as to prevent the recurrence of the pre-war overfishing. They recommend that the North Sea between latitude 52° and 56° and within the Continental coast and the 12- or 15-fathom contour line be closed to steam trawlers and high-power motor vessels for the whole or part of the year. They also recommend transplantation of small plaice from this closed area to the Dogger Bank.

The fishing industry strongly opposes any restriction on fishing outside the three-miles limit, and it is now evident that this objection will be fatal to the adoption of the recommendations of the Plaice Committee. Any restriction of this kind is bound to lead to decreased profits or earnings at the time of its imposition. As a rule traders take a very short view of the circumstances in question, and are not inclined to make personal sacrifices in order that future generations of traders may obtain advantage. They hold that the evidence available does not justify the Government in accepting the recommendations noted above. Would *any* evidence bring about such industrial altruism? It is doubtful. In the present case, however, the evidence that is available has either not been published or it is presented in such a way that it does not easily appeal to the owners of fishing vessels. Obviously, such restrictions as are indicated must be made and enforced against the strong opposition of the fishing trade and with the approval of the public, and if that is to be so, the fullest publicity should be given to all the data on which the recommendations of the Plaice Committee are based. It is understood, however, that the passion for economy on the part of the Treasury and Stationery Office is now preventing the publication of expensive official scientific reports, and, that being the case, the attitude of the trade is, perhaps, quite justifiable.

J. J.

Gametic and Zygotic Sterility.

A FORM of pollen-sterility in which the anthers are aborted and the flowers fail to open is described by Dr. Bateson and Miss Gairdner (*Journal of Genetics*, vol. 11, No. 3) in flax. Some flowers produced a little pollen, and when self-fertilised gave rise only to male-sterile plants. This male-sterile form appeared as 25 per cent. of the F_2 of a cross between a procumbent variety of *Linum usitatissimum* and the pollen of a common flax. Later it was found that the sterility was determined by the pollen of this flax, the procumbent variety being genetically hermaphrodite on both the male and female sides.

In the same periodical Mr. Rudolph Beer makes a study of the cytology and genetics of Fuchsias, in which partial sterility of pollen and supernumerary pollen-grains are well known to occur. He finds that a pure species, *F. arborescens*, produces a large proportion of sterile pollen, while a cross between the distinct species *F. pumila* and *F. alpestris* shows regular pollen-development and very few bad grains. Such results have an interesting bearing on the hypothesis that bad pollen is in itself a criterion of hybridity. Some of the crosses result in "false hybrids" similar to those obtained in strawberries.

An interesting case in which ratios are altered through zygotic sterility, or rather weakness in development of a zygotic type, is described in the same journal. Mr. Bungo Miyazawa describes a dwarf type of barley which apparently arose as a mutation, and without exceptional care is capable of surviving only in the heterozygous condition. Thus dwarf plants when self-pollinated gave 2 dwarfs : 1 tall, but by careful germination of the seeds the homozygous type was enabled to survive, and was found to be an extreme dwarf which was sterile, producing no flowers.

Prof. E. M. East (*Genetics*, vol. 6, p. 311) has studied the partial sterility in hybrids between *Nicotiana rustica* varieties and *N. paniculata*. Nearly all the F_2 plants resemble *rustica*, a few are almost identical with *paniculata*, while many expected combinations of the parental characters are missing. The sterility varies from almost complete abortion of pollen and seeds to nearly complete seed fertility. This followed a condition of high sterility in F_1, in which only about 3 per cent. of the ovules were functional and only 35-55 per cent. of the seeds would germinate. The pollen-sterility of F_1 plants is even higher, probably not more than 0·1 per cent. of the possible grains from the pollen mother-cells reaching functional maturity. Many break down in the reduction divisions, and many apparently perfect grains dry up when the anther opens. Nearly all the F_2 plants show an increased fertility. The results are explained in terms similar to Goodspeed and Claussen's hypothesis of reaction systems. In brief, certain chromosome combinations are non-viable or produce offspring in which again only certain recombinations can survive. Prof. East suggests that many cultivated plants have originated from similar crosses in which a high degree of sterility has been followed by greater fertility in certain surviving strains.

Further light has been thrown on the sterility in wheat hybrids by the fact that the different types of wheat fall into three groups, which appear to have multiples of 7 as their chromosome numbers. Dr. Karl Sax (*Genetics*, vol. 6, p. 399) finds that the pollen-grains show a corresponding increase in size, the average relative volumes being 72 for Einkorn, 94 for Emmer wheats, and 114 for *T. vulgare*. This is to be expected with an increase in chromosome-content. The results of many investigations indicate that, in general, there is fertility in crosses within each group where the chromosome numbers are the same, but more or less sterility in crosses between forms belonging to different groups. Dr. Sax finds that in fertile crosses of wheat species the F_1 grains (endosperm) are larger than in the parent—a phenomenon of hybrid vigour—but in crosses which are partly sterile the grains are small and wrinkled. The degree of sterility may be determined by the amount of grain set, or by the amount of aborted pollen. There is much variability in the size of pollen in partly sterile F_1 hybrids, which is probably due to irregular chromosome distributions.

R. R. G.

Some Aspects of Cotton Growing.

THE great importance of the cotton crop in certain countries has led to special attention being paid to the deterioration in yield and quality that occurs in certain areas and to methods whereby improvements may be effected.

In Egypt (Bull. Imperial Inst. 19, No. 2) the decline in yield may be attributed chiefly to degeneration of the productive power of the soil, the ravages of insect pests, and to agrarian disturbance. To give satisfactory crops cotton, should be grown only once in a three-year rotation, but this limit has frequently been exceeded, with the natural result that the soil ingredients have been drawn upon unevenly, thus upsetting the balance of fertility. This could have been remedied by the judicious use of fertilisers, but for various reasons this has not been carried out. Even where manures have been used much harm has been done by the introduction of noxious substitutes by unscrupulous dealers. Excessive cotton cultivation has also been encouraged by the practice of leasing land for short three-year periods, the highest rents being paid to landowners who permit the greatest amount of cotton to be cultivated within the period of the lease without insisting on the re-establishment of the fertility of the soil for future tenants.

Another harmful factor is the prevalence of waterlogging. Since the Assuan Reservoir came into use, more water has been available for irrigation, and in addition the water table has risen, so that the drainage is now imperfect, and the roots of the cotton plant suffer from asphyxiation due to the consequent lack of air supply. The damage is aggravated by harmful salts which are now brought into solution near the soil level, and by surface evaporation remain within the area of growth of the cotton roots.

Until about 1912 the cotton worm was the most serious insect pest, but was eventually brought under control. Of recent years the pink boll-worm, first discovered near Alexandria in 1911, has become of paramount importance owing to its rapid spread through nearly all the cotton-growing countries of the world. Its life-history and habits rendered impossible the production of late-maturing cotton, as the late-formed bolls are badly attacked and the lint rendered useless for spinning purposes. Legislative measures are now in force for the uprooting and burning of the cotton plants before the end of the year, and for the treatment of the seed by hot air, whereby the resting worms are destroyed while the germinating power of the seed is not affected. It is hoped that the attacks of each pest will thus be reduced, and that the yield of cotton will, in consequence, be increased.

Agrarian disturbances have also caused much trouble, as the cultivators joined in the destruction of the means of transport, whereby difficulties arose in marketing the cotton and also in connection with seed distribution for the next season's crop.

Deterioration of quality has been considered in the case of Cambodia cotton (*Gossypium hirsutum*) grown in India (*Agric. Journ. India*, vol. 16, part 3). For some years after its introduction in 1907 the quality of its lint was good, but of late years it has been asserted that the lint is shorter, weaker, and much more stained than was the case at first. The weakness and staining are attributed to attacks of the pink boll-worm, and the loss can only be cured by the reduction of the pest. The shortness of staple, however, is due to the fact that the first seed distributed included a mixture of types. The early and more vigorous types, with poorer quality staple, were the better suited to the climate and to the rather haphazard methods of cultivation, and therefore flourished at the expense of the better quality types with longer staple. The line of improvement it is proposed to follow is that of isolation of types by means of single-plant selection and self-fertilisation, followed at a later stage by hybridisation to produce a type combining in itself all the most useful characters. If a more productive type can thus be produced and the loss caused by insect pests be controlled, considerable increase of yield per acre may be secured.

In this connection attention may be directed to an article on the commercial utilisation of cotton stalks (Bull. Imperial Inst. 19, No. 1). Enormous quantities of stalks are available after the crop is harvested, and as they afford harbourage for insect pests their destruction is of much importance. Locally the stalks are used as fuel, and in some districts supplies would not be available for other purposes. A fibre resembling that of jute, however, can be obtained from the bark, and possibly the longer fibre might be used as a substitute for the lower grades of Indian jute, and would probably realise rather less than half the price of Bengal jute.

Preliminary paper-making trials indicate that when treated by the caustic soda process, Indian cotton stalks yield paper pulp of fair quality which can be bleached to a pale cream tint, and the results are promising enough to deserve further consideration on the spot in India. Distillation experiments have also been carried out both in Egypt and England; good quality methyl alcohol and acetate of lime have been produced, but the charcoal and tar are of less value. In India the feasibility of distilling cotton stalks successfully would depend upon finding local markets for the products, particularly the charcoal and tar.

The Geographical Distribution of the Palm Pritchardia.

THE Bernice Pauahi Bishop Museum of Honolulu has recently issued (Memoirs, vol. 8, No. 1) an elaborate monograph of the palm genus Pritchardia by the late Prof. Odoardo Beccari and Prof. Joseph Rock. It is mainly the work of Prof. Beccari, and forms part of a larger monograph which he had prepared for later publication in the Annals of the Calcutta Botanic Garden. The material for the monograph has been largely supplied by Prof. Rock, who has discovered twenty-one of the thirty-three species described.

The study of the genus is of special interest from the point of view of geographical distribution. It is one of the most characteristic genera of palms of the Polynesian flora, but has attained its greatest development in the Hawaiian Archipelago, where it is the only palm found. It also supplies one of the most interesting problems in the geographical distribution of the family in the existence of a single species in the New World, namely, in Cuba and the Isle of Pines. This may be compared with the presence in South America of a representative of the African genus Raphia and of the solitary representative of the typical American Cocoineæ, namely Jubæopsis, in South Africa. How the fruits of the progenetrix of the Cuban species were enabled to cross the wide space of ocean between the nearest Polynesian islands and the American continent is a mystery. Prof. Beccari suggests the possibility of the transfer of fruits by means of the violent volcanic phenomena which

must have occurred during the elevation of the Andean ranges; at such a time a water communication may have been established between the two oceans and the fruits of a Polynesian Pritchardia deposited on an island in the Caribbean Sea.

The fruits, which are plum-like in structure, but with comparatively little flesh, vary in the different species from the size of a large pea to that of a date. The smaller ones would attract pigeons, which, though now unknown in Hawaii, may at some time, when greater land connections existed between the remoter islands of eastern Polynesia and those of Papuasia and western Polynesia, have contributed to stock the islands of the Hawaian group. But there is still the difficulty of explaining the presence of large-fruited Pritchardias on the most inaccessible summits of the mountains of Hawaii. Prof. Beccari suggests that these represent a surviving element of the vegetation which covered the plains before the cataclysms which resulted in the elevation of the present mountains and broke into fragments the originally much more extensive land area. The monograph is illustrated by twenty-four plates, mainly reproductions of photographs taken by Prof. Rock.

Agricultural Experiments at Ithaca, N.Y.

THE Report of the Agricultural Experiment Station of Ithaca, N.Y., for 1919 contains a number of memoirs of considerable interest, especially from the botanical and entomological points of view.

Work on the stimulation of growth by various chemical compounds indicates that treatment with potassium permanganate may result in a very marked increase in the root-growth of various woody cuttings. Other compounds of manganese, iron, and boron may show at times a slight stimulating effect, but nutrient solutions are, as a rule, injurious to the root-growth of cuttings. In another paper the effect of manganese compounds on soils and plants is discussed. The general conclusion reached is that with wheat, manganese salts presented in high concentrations exert a toxic effect, but in lower concentrations a marked stimulation is observable. When added to soil, manganese salts were found to form manganese dioxide in proportion to the basicity of the soil and to develop a power to oxidise organic matter.

In genetics two papers deal with chlorophyll inheritance and aleurone colour in maize, and another with the weak awn in certain Avena crosses. In some crosses of awned and awnless varieties (as Burt and Sixty Day) there is an almost complete dominance of the awnless condition, the factor for awning being apparently prevented from operating by an inhibition which is closely linked with the factor for yellow colour in the variety concerned. Environment seems to affect the production of awns, and observations suggest that an increase in the moisture-content of the soil and of its organic matter and nitrogen tends to decrease the number of awns.

Soil conditions are dealt with in memoirs on the translocation of calcium and on the reversibility of the colloidal condition of soils. In the first case it was found that the translocation of calcium through a clayey silt loam soil with a rather large lime requirement is extremely slow, since in the experiment no upward or downward movement of this element was perceptible twelve months after various amounts of calcium salts had been applied to the soil. In the second case it was demonstrated that drying a surface soil once produces as much effect in the colloidal material as repeated dryings alternated with moistenings, the drying producing a change in the colloidal material from which it does not immediately recover on being wetted. The drying indirectly affects the reversibility of its colloidal condition, the change being directly produced through biological and chemical action.

On the bacteriological side attention is directed to the effect of low temperature on soil bacteria and to the number and types of bacteria found in ice-cream during storage. In the soil there appears to be no change in the bacterial flora due to freezing, the bacterial activities being influenced only in so far as the physical properties of the soil are affected. The concentration of the medium, the length of time of exposure, and the degree of cold are the three important factors that determine the power of resistance of the bacteria to low temperature. The death of the bacterial cell when exposed to low temperature seems to be due to the withdrawal of water from the semi-permeable membrane or outer layer of the cell.

An outline is given of the life-histories and methods of control of various insects injurious to the hop in New York, special attention being devoted to the hop grub (*Gortyna immanis*, Guenee) and the hop redbug (*Paracalocoris Hawleyi*, Knight). The hop grub causes considerable financial loss, and in years when the insects are plentiful they may cause an almost total loss to some growers. The larvæ damage various parts of the vine, working in the buds, stem, and roots, thus weakening the plants in various ways. For control, clean cultivation is advised, with a ploughed border several yards wide round the field. The use of carbon bisulphide as an insecticide is unsatisfactory, but paradichlorobenzine has been successful when added to the soil of each hill in May.

The plant-lice injuring the foliage and fruit of the apple (*Aphis pomi*, de Geer, *A. sorbi*, Kaltenbach, and *A. avenæ*, Fab.) are described and fully illustrated, and the first part of a detailed systematic account of the crane-flies of New York is issued, dealing with the distribution and taxonomy of the adult flies.

W. E. B.

The Lhota Nagas.

AT a meeting of the Royal Anthropological Institute held on March 14, Dr. W. H. R. Rivers, president, in the chair, Mr. J. P. Mills, of the Indian Civil Service, read a paper on the Lhota Nagas of Assam. He said that in spite of its long contact with the plains of Assam, this tribe has retained its primitive dress and customs. It occupies a portion of the Naga Hills lying to the S.E. of the Brahmaputra Valley, and numbers some 18,000 souls. Like the Angamis, the Lhotas trace their origin to a mythical hole in the earth near the Kezakenoma stone. In dress they resemble closely their neighbours, the Aos, the men wearing a small apron and body cloths of various patterns, and the women a small skirt of very dark blue, with a light blue median band. Warriors in full dress wear human hair tails, elaborate baldricks with fringes of goat's hair dyed scarlet, and bear's hair wigs ornamented with hornbill feathers.

The villages, which are permanent, may contain any number up to 300 houses and are built on the tops of the ridges. The highest is at about 5000 feet. Each village contains one or more "bachelors' halls" in which boys and unmarried men sleep. In the middle of the village stands the head-tree, usually a *ficus*, on which heads taken in war were hung. Under it are

kept the "luck-stones" of the village, to which the Lhotas attach great importance. Other "luck-stones" are kept in the "bachelors' halls" and in the houses or granaries of individuals. Cultivation is of the shifting type known as *jhuming*, and there are numerous ceremonies connected with it.

The tribe is composed of three *phratries*, each of which contains a number of clans, which are in turn often subdivided into kindreds. Formerly a man was forbidden to marry a woman of his own *phratry*, but now intermarriage in the clan is often allowed provided the parties are of different kindreds. The classificatory system of relationships obtains. Inheritance is in the male line. Each village is run as a separate unit by an informal council of old men, and has an old man duly qualified who takes the lead at religious ceremonies. They believe in no Supreme Being, but in a world of godlings above the earth. The underworld is occupied by the dead, and elaborate precautions are taken at funerals to ensure that the soul goes there in comfort. Each male Lhota tries to perform the full series of feats of merit, and, like the Angami, sets up a monolith to mark their completion. A man's cloth varies according to the stage which he has reached in the series.

The Development of Ceylon.[1]

CEYLON has large and successful agricultural industries, and in 1916 a Commission was appointed to consider the development of existing industries and the establishment of new ones, in other branches of activity. The report of the Commission has just been issued, and is a very practical document, fully recognising that scientific knowledge is only one item, and that not the chief, in ensuring success. Many industries, desirable in themselves, do not offer sufficient financial prospects to attract any one away from the established agricultural and other trades.

The report goes on to say, "We have been profoundly impressed by the importance of scientific research in the progress and development of most of the industries we have examined"; and this theme is developed at some length, the final recommendation being that as private individuals can rarely afford the cost of the necessary research, this should be largely the affair of the Government, which is urged to establish a Bureau of Industry and Commerce, that should aim at a greater degree of co-ordination between the various scientific departments, and prevent overlapping of work. It should also establish a central Economic Museum, collect and collate statistics, foster new industries, aid them with scientific and other advice, and do other things. This would involve the establishment of a staff of research workers, and it is to be hoped that they may be generously paid, for, as it has been said, "A paternal Government may desire investigations to be made on some defined subject, and may duly engage an explorer to map that bit of country. . . . Then the poor sportsman, if he is to carry out his part of the agreement, is no longer free. And in that case he deserves good pay for the surrender of his freedom."

It is first pointed out that industries cannot be established without power, and as Ceylon has no coal this power must be hydro-electric. There are indications, however, that some scheme of utilisation of the considerable amount of water power that runs to waste in the hills may soon be put in hand.

Various possible industries are then considered, in which, bearing in mind the above considerations, it is conceivable that success might be attainable. Cement, for example, is considered to have little prospect, inasmuch as Ceylon could not consume the whole output of a factory large enough for proper efficiency. Spinning and weaving, on the other hand, offer good prospects, if the cultivation of cotton can be extended, for there is a large local demand, and the excellent wearing capacity of the cloth made from the short-stapled Indian cotton has already been fully proved.

The possibility of providing the wood used for the making of the vast numbers of chests used for packing tea, rubber, etc., is then considered, and it is thought that, with proper attention to seasoning, Ceylon should be able to supply all her own material, provided that the requirements of the grower of the wood, the maker of the box, and the user of the same, can be properly harmonised—a matter which would fall to the suggested Bureau.

For the encouragement of home industries, such as weaving, silver and brass work, embroidery, and the like, the establishment of a central School of Arts and Handicrafts is recommended.

The question of the fisheries is then dealt with, and it is pointed out that while there is more fish available in the sea than the island requires, it nevertheless imports to the value of about Rs.6,000,000 yearly. It is suggested that a Department of Fisheries be established, in place of the Marine Biological Department so ably carried on by the present Director of the Colombo Museum in addition to his other duties. This new department should attend, among other things, to increasing production, to improvement in methods of curing, to canning (for example, of sardines, which are plentiful), to the manufacture of fish manure and oils, to freshwater fisheries, pearl fisheries, chank, window-pane oyster, and bêche-de-mer fisheries, to encouragement of research, and other things, in all of which there seems to be great opening.

It is further suggested that experiments should be made with such industries as the manufacture of glass, cyanamide, paper, soap, etc.; and the improvement of the mining industry is also considered.

In conclusion, stress is laid upon the necessity for wise action by the State in regard to provision of power, and establishment of the Bureau above mentioned, when it is considered that industries dependent upon forestry and fishing would show the most promise. It is also urged that the youth of Ceylon be given the opportunity, by technical training, etc., of taking part in any future industrial development. The whole report is of a practical and statesmanlike character.

[1] Report of the Industries Commission, Ceylon. (Sessional Paper 1 of 1922.)

University and Educational Intelligence.

CAMBRIDGE.—The Allen Scholarship has been awarded to J. C. Burkill, Trinity College.

The annual report of the Appointments Board shows a total of 349 men placed in the past year, the highest figure for the past nine years. In view of the prevailing conditions in the industrial and commercial world, this is a satisfactory report. The chief subjects in which men have been placed by the Board are: Educational appointments, 143; administrative appointments in commerce and industry, 65; manufacturing and technical appointments, 47.

OXFORD.—Mr. A. L. Dixon, Fellow and Tutor of Merton College, has been appointed Waynflete Professor of Pure Mathematics in succession to Prof. E. B. Elliott.

THE honorary degree of Doctor of Science has been conferred on Sir Thomas Muir by the University of Cape Town, in recognition of his researches in mathematics and mathematical history. Sir Thomas Muir was Superintendent-General of Education for

Cape Colony from 1892 to 1915, and for the greater part of that period he served as a member of the council of the University.

THE Royal Academy of Belgium announces that a triennial prize of 2500 francs, to be known as the Prix Joseph Schepkens, for the best experimental work on the genetics of vegetables, has been established.

THE Research Chair of Medical Psychology in the University of Queensland, Brisbane, has been filled by the appointment of Dr. J. P. Lowson, University Demonstrator in Experimental Psychology at Cambridge. It is expected that Dr. Lowson will arrive in Brisbane early in this month.

THE Hull Corporation recently endeavoured to purchase nineteen acres of land on the outskirts of the city, adjoining the Hull Training College, for the purpose of a Technical College, the present building, near the centre of the city, being too small and inconvenient. The Board of Education, owing to national financial stringency, turned the matter down. The Rt. Hon. T. R. Ferens, formerly M.P. for East Hull, has now purchased the land for ten thousand pounds and presented it to the Hull education authority. Mr. Ferens has previously given about 40,000*l*., for the erection of a new Art Gallery, 10,000*l*., for the purchase of pictures, besides other amounts for the erection and endowment of almshouses, and in numerous other ways has placed the citizens of Hull under a deep debt of gratitude.

THE interest in the eighth report of the Carnegie United Kingdom Trust for the year ending December 31, 1921, centres round two schemes to which the Trust has definitely committed itself—(*a*) to provide facilities for reading in the rural districts, and (*b*) to supplement the resources of library authorities throughout the United Kingdom by regional centres of book distribution. The launching of these two schemes was preceded by a very careful sufvey of the whole question of library policy, the results of which are beginning to bear fruit. There are now 39 county schemes in operation in Great Britain, *i.e.* schemes administered from county headquarters, from which boxes of books are circulated to the village centres—the distributing agent in the village being usually the local teacher. Thus the county library and education authorities are brought into direct connection—the local teachers working under the direction of the county librarian. This method has worked satisfactorily. Past experience, however, teaches that little value is to be placed on initial success. When the novelty of the experiment and of the books circulated wears off, the interest of readers wanes and the system falls into disuse. Against this the Trust has wisely provided by the provision of regional book stores—of which three centres are already established in London, Dunfermline, and Dublin—the last named being still in its embryo stage. In Wales the National Library at Aberystwyth has for some years supplied this want. In these centres a large and well-selected stock of books has been accumulated which should go far toward satisfying the requirements of serious readers not only in the villages but also in the smaller borough and urban districts. Thus equality of opportunity now exists throughout Great Britain for self-education, and this result has been secured with a minimum expenditure on the machinery of administration. Amongst the miscellaneous grants we note with pleasure that a generous, though final, donation has been made to the Library Association in respect of its "Subject Index to Periodicals." We understand that the Class List "Science and Technology" for 1917–19 is in the press and will be issued shortly.

Calendar of Industrial Pioneers.

March 23, 1875. Thomas Lloyd died.—Trained as a shipwright at the School of Naval Architecture at Portsmouth, Lloyd was detailed by the Admiralty for duty with the early naval steam vessels, and ultimately became the first Engineer in Chief of the Navy, a post he held from 1847 to 1869. He was born in 1803, and his services extended from the introduction of steam into the Navy to the development of the first mastless steam ironclad, H.M.S. *Devastation*.

March 24, 1879. Karl Karmarsch died.—Born in Vienna in 1803, Karmarsch founded, and for forty-five years directed, the Polytechnic at Hanover, and wrote valuable works on mechanical technology.

March 25, 1864. Francis Baird died.—Second son of Sir Charles Baird, the founder of the well-known works at St. Petersburg, Baird for many years was sole proprietor of the establishment, and as such carried out numerous important contracts for the Russian Government.

March 25, 1905. Bruno Kerl died.—A distinguished German metallurgist, for thirty years a professor at the Berlin School of Mines, Kerl was the author of valuable treatises, and for thirty-eight years edited a mining and metallurgical journal.

March 25, 1912. Antonio Pacinotti died.—One of the pioneers of the dynamo, Pacinotti was educated at Pisa, where his father was a professor. He served in the Garibaldean wars, and on his return to Pisa in 1860, at the age of 19, constructed the ring-armature dynamo, a form of dynamo re-invented ten years later by Gramme. Though unnoticed at first, Pacinotti's work ultimately received recognition and he was awarded various honours. He held professorships at Florence, Cagliari, and Pisa, where he died.

March 26, 1865. Thomas Hancock died. — The great pioneer of the British rubber industry, Hancock took out his first patent in 1820. He afterwards perfected a process of mastication, and in 1843, having seen samples of the "cured" rubber of Goodyear, patented a method of "vulcanising" rubber by sulphur, and was the first to make vulcanite or ebonite. With his brothers he founded the firm of James Lyne Hancock. In 1857 he published his "Personal Narrative of the Origin and Progress of the Caoutchouc or Indiarubber Manufacture in England."

March 26, 1858. John Seaward died.—In 1824, after experience in many branches of engineering, Seaward opened the Canal Ironworks at Millwall, and became one of the principal builders of marine engines for the Navy. Assisted by his brother Samuel, he made many improvements in paddle-wheel machinery, and introduced the "Gorgon" type of direct-acting engine.

March 28, 1919. Henry Wilde died. — Left an orphan at 16, Wilde began life as an engineering apprentice in Manchester. In 1856, at the age of 23, he set up in business as a telegraph and lightning conductor expert, achieving his first success with an alphabetical telegraph. In 1863 he began his work on the dynamo, which with his electro-chemical discoveries laid the foundation of his fortune. He retired from business in 1884, devoted much time to scientific research, and became well known for his generous gifts to scientific institutions.

E. C. S.

Societies and Academies.

LONDON.

Association of Economic Biologists, February 24.—Sir David Prain, president, in the chair.—J. **Rennie**: The present position of bee-disease research. There is a general similarity of symptoms in all adult bee diseases. With the recognition of the parasite, *Nosema apis*, in association with bee disease there has been at the same time a failure to appreciate a preponderance of cases of disease from which this organism was absent. Recent work at Aberdeen has shown that there are at least three adult bee diseases of importance prevalent in this country—all of which have hitherto been called Isle of Wight Disease. Besides Nosema disease, there are Acarine disease and Bee Paralysis. At the present time Nosema disease is less common than Acarine disease, but appears to be maintained to some extent by the importation of foreign bees, a proportion of which contain the parasite, *Nosema apis*. Acarine disease is the more formidable malady; its causal agent is a Tarsonemid mite which breeds in the thoracic tracheæ and feeds on the blood of the bee. An important feature in this disease, which has hitherto rendered control measures difficult, is the long period of infestation while the mite is being established in the colony, during which time the presence of the parasite is unsuspected. The systematic examination for this parasite of all stocks should be the first step in control. Bee paralysis, described by the Swedish investigator Turesson as an intoxication due to phenolic acids developed in the combs and pollen by the growth of various moulds, has also been recognised in Great Britain.—J. **Rennie**: Polyhedral disease of tipula species. Larvæ of *Tipula paludosa*, the fat body cells of which contain polyhedral bodies in the nuclei, do not complete their development; they die before pupation. This affection, known in various Lepidopterous larvæ, has not hitherto been observed in Diptera. The polyhedra appear to be developed in association with a virus. Infection by feeding is readily produced, and polyhedral bodies develop within the fat body cells in some six or seven days.

Linnean Society, March 2.—Dr. A. Smith Woodward, president, in the chair.—R. E. **Holttum**: The flora of Greenland. During the summer of 1921 a visit was paid to Disko Island and parts of the west coast of Greenland. The most widely-spread vegetation is a low heath of *Empetrum nigrum Cassiope tetragona*, etc. In specially protected localities a scrub of *Salix glauca* was found, which may reach eight feet in height, accompanied by herbaceous plants of southern type. In unfavourable situations there are isolated plants of resistant herbaceous and woody species. The flora of the whole of Greenland consists of 416 species of vascular plants, of which 18 per cent. are high arctic in type, 22 per cent. widely distributed, and 60 per cent. of southern type.—J. **Walton**: The ecology of the flora of Spitsbergen. The largest number of species in Spitsbergen occurs where continental conditions are approached; *e.g.* at the head of Klaas Billen Bay, near the centre of West Spitsbergen, an area of about 5000 square kilometres contains 90 per cent. of the species of vascular plants occurring in Spitsbergen. Three vegetational zones appear: raised shingle beach, alluvial land between mountain and beach, and scree slopes. The development of the flora of the two former can be traced to an intertidal zone which resembles the salt-marsh formation of lower latitudes.—Sir W. A. **Herdman**: Spolia Runiana—V. Summary of results of investigation of the plankton of the Irish Sea during fifteen years. The spring phytoplankton maximum ranges from March to June, and is chiefly composed of diatoms which vary greatly from year to year in maximal haul, up to over 200 millions. This immense diatom curve can be resolved into an earlier crest in April or May, chiefly formed of *Chaetoceras*, and a later in June, chiefly formed of *Rhizosolenia*. The Dinoflagellate maximum follows about a month later than the diatoms, and varies in our records from May to July (rarely August). The Copepod maximum is later again, and ranges from June to October. The largest hauls of plankton are obtained, during daylight, at a level of from 5 to 10 fathoms. The Irish Sea plankton contains from 30 to 60 per cent. of Oceanic forms, the rest are Neritic. Mid-winter and mid-summer are more oceanic in character than the intervening months. A comparatively small number of genera of Diatoms and Copepoda are the dominant organisms of the plankton, and these are the important food-matters for the nutrition of higher animals in the sea. It is probably impossible to draw numerical conclusions as to the population of large sea-areas from few and small samples of the plankton, for series of vertical hauls taken at the same spot in rapid succession show variation up to 50 per cent. The distribution of plankton in the sea is not uniform, and many animals such as Copepoda are present in swarms or patches. As suggested by Hjort, the survival of newly hatched food-fishes in early spring, upon which the prosperity of future commercial fisheries may depend, is possibly determined by the amount of phytoplankton present at the time.

Institute of Metals, March 8.—G. D. **Bengough**: Notes on the corrosion and protection of condenser tubes. Specific recommendations are made for the guidance of manufacturers of tubes and condenser plants.—F. **Adcock**: The internal mechanism of cold-work and recrystallisation in cupro-nickel. Cast cupro-nickel, annealed until homogeneous, can withstand considerable cold working and yet be sufficiently hard to permit of rapid preparation for micro examination. Material subjected to reductions of 50 per cent. and 88 per cent. by cold working was examined to investigate the nature and direction of certain strain planes passing through most of the crystal grains of the distorted metal. Cold-worked specimens annealed for fixed periods at progressively higher temperatures were also examined. The effect of annealing is at first the accentuation of the "strain" markings, followed at higher annealing temperatures by the appearance of new crystal grains, which, if on the sites of the "strain" lines, are frequently elongated in the direction of these lines. The Brinell hardness of the cold-worked metal did not begin to fall appreciably until the annealing temperature was such that new crystal grains were readily discernible under the microscope.—Research Staff of the **General Electric Company** (London): The effect of impurities on recrystallisation and grain growth. Tungsten wires were prepared containing known quantities of thoria, alumina, silica, lime and the alkali metal oxides, in various proportions, and changes in crystal structure on annealing at 2500° were followed. The refractory oxides, which ultimately segregate in the grain boundaries, exert a definite resistance to grain-growth. The alkali metal oxides have no influence upon grain-growth, but an exaggerated growth takes place on annealing tungsten containing a few tenths per cent. of both a refractory oxide and an alkali metal oxide. Single crystals occupying the entire cross-section of the wire, and three hundred times as long as their diameter, are formed on annealing for a

fraction of a minute. Crystal growth and recrystallisation in metals probably depend on a difference in vapour pressure between neighbouring crystal grains. This explains the known phenomena in relation to the effect of strain, grain-size, and temperature in regulating recrystallisation and grain-growth on annealing.—H. **Moore** and S. **Beckinsale**: Further studies in season-cracking and its prevention: condenser tubes. The properties of various condenser tubes were determined before and after annealing at temperatures in the range 250°-325° C. By annealing experiments on flat strips of condenser-tube brass elastically bent to an arc of a circle and thus initially stressed to a known amount the effects of initial hardness, initial stress, time, and temperature, on the reduction of initial stress by low-temperature annealing were determined quantitatively. The rate of reduction of stress at the lower temperatures is rapid, but slows down when the stress has been considerably reduced. The higher the initial stress the higher is the remaining stress in brass of the same hardness, and the higher the hardness the lower is the remaining stress for a given initial stress. A temperature of 250°-275° C. is very effective in restoring elasticity in the overstrained material. Treatment at 280°-300° C. for 30 mins. reduces initial stress to a safe limit without injury to, and in some cases with marked improvement in, the strength of the tube.

March 9.—W. **Rosenhain**: Some cases of failure in "aluminium alloys." Some "aluminium alloys" undergo distortion and disintegration; they usually consist mainly of zinc and are not properly described as aluminium alloys. Such alloys, consisting largely of zinc and also containing aluminium and copper, are unstable at ordinary temperatures and liable to changes of dimension and disintegration. True light alloys of aluminium (consisting mainly of aluminium), if properly prepared are free from any risk of serious growth or disintegration.—F. C. **Thompson** and E. **Whitehead**: Some mechanical properties of the nickel-silvers. The effect of annealing at different temperatures, and the different rates of cooling after annealing, upon the tensile properties, the Arnold alternating stress values, and the Erichsen values of hard-rolled alloys containing 10, 15, and 20 per cent. nickel were examined. Changes occur at about 300° C. and 550° C. Annealing at 300° C.-400° C. results in a material of very low ductility. The best annealing range for the 10 per cent. nickel alloy is 725° C.-825° C.; for the 15 per cent. nickel, 700° C.-800° C.; and for the 20 per cent. nickel alloy, about 800° C. As the nickel content is raised the tensile strength is raised, while the maximum ductility is considerably reduced. As regards Brinell hardness almost the whole of the softening takes place in the first two hours. The greatest ductility and the highest Erichsen values are obtained after annealing for 1½ hours for small samples. There is little to choose between annealing for a short time at a high temperature and for a longer time at a low temperature. The alloys can be heated to a high temperature without deterioration, especially when the sample is protected from oxidation. The Erichsen tests show good results even after annealing at 850° C.—D. **Hanson** and Miss M. L. V. **Gayler**: A further study of the alloys of aluminium and zinc. Alloys containing 70, 60, 50 per cent. of zinc when slowly cooled to 284° C., after prolonged annealing at 420° C. and quenched are duplex in structure. A redetermination of the solidus from 81-20 per cent. zinc showed that the line representing the peritectic reaction extends to a composition of 70 per cent. zinc as against 40 per cent. zinc in previous diagrams. Microscopic examination of alloys, following special heat-treatment, disproved the existence of the compound Al_2Zn_3, and showed that the nature of the change in the alloys at 256° C. in Rosenhain and Archbutt's diagram is identical with an ordinary eutectoid transformation, the decomposition of the β-phase leading to the "pearlitic" structure commonly found in the alloys. Below 256° C. the solubility of the α-constituent in the γ-constituent decreases with the temperature. Alloys containing the β-constituent harden spontaneously at room temperature after being quenched from above 256° C.; those containing the γ-constituent showed the same property in a much less marked degree.—A. **Westwood**: The assay of gold bullion. The assay sample is not cupelled but is melted and balled up under steam or an inert gas. For the usual inquartation copper is recommended in place of silver.—C. A. **Edwards** and A. J. **Murphy**: The rate of combination of copper and phosphorus at various temperatures. When using ½-inch copper rod the maximum rate of increase of phosphorisation in phosphorus vapour for a given rise of temperature occurred at 640° C. Phosphorisation at this temperature is quick and safe, and the operation can be controlled so as to prevent the formation of any liquid, while it is impossible to obtain an alloy containing more than the percentage of phosphorus which is required commercially.

CAMBRIDGE.

Philosophical Society, February 27.—Mr. C. T. R. Wilson, vice-president, in the chair.—G. F. C. **Searle**: (1) An experiment illustrating the conservation of angular momentum. A horizontal board is suspended by a practically torsionless silk thread. Attached to the board is a vertical pivot about which an inertia bar turns balanced by a suitable counterweight. The inertia bar is held by a thread in a definite position against the action of a spring and then the thread is burned. The spring turns the bar until its motion relative to the board is arrested by a stop and the board turns in the opposite direction. The ratio of the angles turned through by board and bar is equal to the ratio of the moments of inertia of the bar about its pivot and of the whole system about its axis. This ratio is found by means of a torsion wire. (2) A focal line method of determining the elastic constants of glass. Light from a collimator, with cross-wires in one focal plane, falls on the surface of a bar of glass. The reflected beam falls on a converging lens system which is adjusted so that the origin point on the surface is in one focal plane. A ground-glass screen on an optical bench is adjusted to be in the other focal plane. When the bar is bent, the cross-wires are set horizontal and vertical and the position of the focal lines of the reflected beam is determined. When the bar is twisted, the cross-wires are set at ±45° to the horizontal and similar measurements made. The glass bar is replaced by a concave spherical mirror and the measurements repeated. Young's modules, Poisson's ratio and the rigidity can be calculated.—G. **Stead** and E. C. **Stoner**: Low voltage glows in mercury vapour. The effect of varying pressures and filament temperatures on the glow potential of mercury vapour, and on the current changes accompanying the appearance and disappearance of the glow were investigated. The glow could be obtained in a dome-shaped form of variable length. At higher pressures the glow point occurred below the ionisation potential.—E. V. **Appleton**: An electric wave detector. The thermionic current of a diode vacuum tube in which the electrons move with very small velocity is deflected by the direct action of electromagnetic radiation.

The resulting reduction in the thermionic current is used to indicate the field strength.—E. B. **Ludlam**: An attempt to separate the isotopes of chlorine. Hydrogen chloride at a pressure of about two centimetres of mercury was passed over (*a*) a water surface, (*b*) ammonia gas, so that a small fraction was retained uncombined. The chlorine was weighed as silver chloride. Any increase in weight could be attributed to experimental error.—M. H. **Belz**: The measurement of magnetic susceptibilities at high frequencies. A heterodyne beat method is described, in which changes in inductance are produced by insertion of the specimen inside one of the oscillating coils. Susceptibility is calculated from the change of beat note. The range of frequency employed was 3×10^5 to 4×10^6 per second, and the results show that, up to this point, frequency has no effect.—G. H. **Henderson**: Note on an attempt to influence the random direction of a particle emission. On applying a magnetic field to radium emanation no change could be detected in the ionization due to beams of α rays parallel and perpendicular to the field.—J. E. P. **Wagstaff**: Determination of the coefficient of rigidity on a thin glass beam.

Dublin.

Royal Dublin Society, February 28.—Dr. J. A. Scott in the chair.—J. **Joly**: A new method of finding the discharge of rivers. This is a modification of the method of chemical hydrometry. A small quantity of uraninite in solution and diluted to a suitable volume is supplied into the river at a uniform rate for a period of 15 or 20 minutes. At a point lower in the river samples of water are taken. These, after a suitable interval, are examined for radium emanation. A river of 10^4 litres per second would require about 300 grams of pitchblende for a measurement aiming at an accuracy of one per cent. Ordinary chemical hydrometry would be much more costly and troublesome.—J. G. **Rhynehart**: On the life-history and bionomics of the flax flea-beetle (*Longitarsus parvulus*, Payk.), with descriptions of the hitherto unknown larval and pupal stages. This flea-beetle is a serious flax pest in Ireland. The adults feed on the leaves of the flax seedlings in May and early June and often destroy large areas. From eggs laid in the soil by over-wintered females are hatched minute larvæ which burrow into and feed upon the roots of the flax plants. Pupation occurs in the soil after about a month of larval life, and a new brood of beetles emerges during the last week of July and the first week of August. Various suggestions for controlling the pest were discussed, and the results of field experiments point to the fact that Bordeaux mixture tends to repel attacks.—E. J. **Sheehy**: The influence of feeding on milk fat. An investigation into the effect of increasing or decreasing the ration of three experimental goats indicated that the percentage of butter fat in milk may be increased to a maximum figure, or may be decreased, according to the mode of feeding. Fat, starch, or protein, when added to a poor ration, may raise the percentage of butter fat.—L. B. **Smyth**: On a variety of Pinite occurring at Ballycorus, Co. Dublin. A mineral occurring at the edge of the Leinster Granite is shown to be a hitherto undescribed variety of Pinite.

Edinburgh.

Royal Society, March 6, 1922.—Prof. F. O. Bower, president, in the chair.—Prof. J. G. **Gray** and Capt. J. **Gray**: Solutions of the problem of the vertical on moving vehicles with special reference to aircraft:—The Gray Gyroscopic Stabilisers. Prof. J. G. Gray communicated this paper on the action of various forms of the Gray Stabiliser, an instrument which was brought to the notice of the British Government early in 1915, and was adopted by the Royal Naval Air Service in 1917, and in 1918 received the approval of the Research Council of America. In 1918 Prof. Gray was invited by the American Government to visit America with a view to developing the instruments to the utmost for use in the American Aerial Services. Unfortunately, for reasons which cannot now be given, the instruments were not used by the British Services over the German lines. The Gray stabiliser does not aim at stabilising an aeroplane as a whole, but provides means whereby instruments of precision used on aircraft, such as horizon mirrors, bombsights, navigational sights, cameras, etc., may be stabilised with respect to the vertical and the horizontal, against both pitching and rolling motions of the aeroplane or airship. This stabiliser finds and maintains the true vertical (the direction assumed by the thread of a simple pendulum as set up in a room) with the utmost exactness on an aeroplane, and is thus available for trimming the aeroplane during cloud flying. The instrument consists of a main stabilising gyroscope, or gyroscopes, attached to the aeroplane by means of a gimbal frame and two sets of pivots. The instrument to be stabilised forms part of the pivoted system. Also forming part of this system is an erector consisting of a member which rotates slowly, on a vertical spindle, in the direction of spin of the main gyroscope, or gyroscopes. This member is provided with a set of compartments, each of which contains a solid spherical steel ball. The compartments are so shaped that, when the pivoted system is inclined to the vertical, the balls automatically arrange themselves so that the device is erected into the vertical by gyroscopic action, when the balls then automatically arrange themselves as a balanced system. An explanation was given of the various forms of erectors which had been devised; and it was shown how in each case the device was given a sense, so to speak, of the true vertical, but was rendered blind to the apparent vertical during curved flight. A bombing aeroplane, just previous to running up to a target, executes a rapid turning movement. The Gray stabiliser permits of all such manœuvres being carried out without the introduction of errors. The pioneer instruments, as tested on aeroplanes by R.N.A.S. officers in 1917, using sun-shadow methods of testing, methods which permitted of the accuracy of the instrument being ascertained beyond dispute, were found to have an accuracy of $\frac{1}{10}$th of a degree, or for bombing purposes an accuracy of about 25 feet on the ground from a height of 15,000 feet. The instruments were absolutely undisturbed by pitching and rolling motions of the aeroplane, even when the flying was carried out with the aeroplane side-on to half a gale of wind. The authors of the paper had been working continuously with a view to perfecting these gyroscopic inventions and were in a position to construct stabilisers, for use on aeroplanes and battleships, which would yield for navigational purposes, and for purposes of bombing and gunnery, an accuracy of one or two minutes of angle at the outside. Gray stabilisers for use with cameras are being constructed for use in the U.S.A. In conclusion Prof. Gray expressed his thanks to the War Committee of the Royal Society of Edinburgh, which in 1915 encouraged his researches in every possible way.—H. W. **Brolemann**: Myriapods collected in Mesopotamia and N.-W. Persia by W. Edgar Evans, B.Sc., late Capt. R.A.M.C. Seventeen species—twelve Chilopoda (centipedes) and five Diplopoda (millipedes)—mostly collected around Amara on Tigris and Ruz, N.-E. of Baghdad, are recorded. Five species and three

sub-species are described as new, and a new genus, *Calyptophyllum*, is erected for the reception of two of the Millipedes.

PARIS.

Academy of Sciences, February 27.—M. Emile Bertin in the chair.—M. E. I. Fredholm was elected Correspondant of the Academy for the section of geometry, and M. Henri Jumelle Correspondant of the Academy for the section of botany.—T. **Carleman**: The series $\Sigma\frac{A_\nu}{z-a_\nu}$.—S. **Sarantopoulos**: A theorem of M. Landau.—E. **Cartan**: A generalisation of the notion of curvature of Liemann and torsional space.—P. **Fox**: Measurements of stellar parallaxes at the Deadborn Observatory (United States). A table of the parallax of 34 stars, supplementing earlier lists given in 1919 and 1921.—T. **Moreux**: A new theory of the formation of the spiral nebulæ and of the solar system.—G. **Perrier**: Compensation of the differences of altitude of a chain of triangles of the first order. Application to the triangulation of the meridian arc of the equator.—M. de **Laroquette**: Measurement of the mean penetrating power of a bundle of X-rays by a new radio-chromometric method. Ten holes are bored in a sheet of lead, and these receive in turn known fractions (from 1 to 50 per cent.) of the total exposure. Twelve other holes are made in the same plate, and in these sheets of metal are placed discs possessing filtering power expressed in millimetres of aluminium, up to 66 mm. The scale thus obtained has been compared with Benoist degrees and possesses advantages over the latter in having a wider range and in being applicable to all radiations.—P. de la **Gorce**: The measurement of power by the differential dynamometer.—M. **Chapas**: The solubility of the isomeric toluic acids in the three xylenes. The para-acid is very slightly soluble in the three xylenes; the meta-acid is more soluble, but the differences from the ortho-acid are insufficient to form a method of separation.—A. **Poucholle**: Contribution to the study of tempering.—P. **Job**: The electrometric study of electrolysis, under the action of baryta, of some complex amine cobalt compounds.—J. B. **Senderens** and J. **Aboulenc**: The catalytic preparation of the cyclohexanetriols. Pyrogallol in alcoholic solution is rapidly reduced by hydrogen in the presence of nickel under a pressure of 40 to 50 kilograms at a temperature of 140° C. The reduction is complete and the product consists of a mixture of two isomeric pyrogallites (trihydroxy-cyclohexanes). Phloroglucinol, in aqueous solution, undergoes reduction to phloroglucite under similar conditions.—M. **Godchot** and P. **Brun**: Some derivatives of suberone. The products of reduction of suberone by calcium hydride are described and also the preparation of dibromosuberone.—E. **Grandmougin**: The halogen derivatives of the isatins.—A. **Schoep**: Dewindtite, a new radioactive mineral. This mineral is found mixed with chalcolite in the Belgian Congo. It is a lead phospho-uranate of the composition $4PbO$, $8UO_3$, $3P_2O_5$, $12H_2O$.—C. **Jacob**: The structure of North Annam and Tonkin.—J. **Savornin**: Stratigraphical and tectonic observations at the north-east frontier of Morocco.—J. **Thoulet**: The neutral lines of submarine coast sediments. The agitation of the sea sorts out the minerals of the sea floor and the results are permanent, as the same results are always obtained in the same locality.—A. **Němec** and F. **Duchoň**: A new indicating method for evaluating the vitality of seeds by the biochemical method. The method is based on the assumption that the activity of the catalase present is a measure of the vitality of the seed. The catalase is determined by measuring the amount of oxygen evolved by the action of hydrogen peroxide. A table of results for seeds of various dates between 1891 and 1920 comparing the catalase found with the percentage of germination proves the utility of the process.—MM. **Warcollier** and **Le Moal**: The progressive disappearance of free sulphurous acid in preserved apples.—L. **Mercier**: Contribution to the study of the regression of an organ; the vibrating flight muscles of *Apterina pedestris* during nymphosis.—L. **Roule**: A rare genus of deep-sea Japanese fish, rarely found in the North-African Atlantic Ocean.—T. **Monod**: The morphology of the buccal parts in the male of *Akidognathia halidaii*.—A. **Policard** and G. **Mangenot**: The action of temperature on the cellular chondriome. A physical criterion of mitochondrial formations.—H. **Grenet** and H. **Drouin**: A bismuth compound of the aromatic series and its therapeutic activity. An account of the therapeutic action of a phenol derivative containing bismuth, concerning the preparation and composition of which no details are given. Its antisyphilitic action is comparable with that of the arsenobenzines.

Diary of Societies.

FRIDAY, MARCH 24.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—Prof. H. E. Armstrong: The Indigo Situation in India.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—Prof. N. Bohr: The Effect of Electric and Magnetic Fields on Spectral Lines (Guthrie Lecture).

INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—Capt. R. P. Stanford: Cheap Transport: Heat and Power, with Special Reference to the D. J. Smith Gas Producer.

INSTITUTION OF PRODUCTION ENGINEERS (at Institution of Mechanical Engineers), at 7.30.—E. Fairbrother: Inspection Methods.

JUNIOR INSTITUTION OF ENGINEERS, at 8.

ROYAL SOCIETY OF MEDICINE (Epidemiology and State Medicine Section), at 8.—Dr. J. Brownlee and Dr. M. Young: The Epidemiology of Summer Diarrhœa.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Prof. F. G. Donnan: Auxiliary International Languages.

SATURDAY, MARCH 25.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radioactivity (4).

MONDAY, MARCH 27.

INSTITUTE OF ACTUARIES, at 5.—G. W. Richmond: Austrian National Life Tables.

ROYAL SOCIETY OF ARTS, at 8.—G. Radcliffe: The Constituents of Essential Oils (Cantor Lectures), (2).

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—A. Livingston: The Experimental Production of Arthritis.

TUESDAY, MARCH 28.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Dr. J. W. Evans: Earth Movements (1).

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. A. Feiling: The Interpretation of Symptoms in Disease of the Central Nervous System (Goulstonian Lectures), (3).

ROYAL SOCIETY OF MEDICINE (Medicine Section), at 5.30.—Dr. O. Heath: The Natural Cure of a Common Cold.—Dr. T. I. Bennett and Dr. Dodds: Observations of Cases involving Disorders of Secretion in the Upper Alimentary Tract.
INSTITUTE OF MARINE ENGINEERS, at 6.30.—E. A. Evans: Petroleum and Lubrication.
ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—A. C. Banfield: The Trist Three-colour Exposure Camera.—General Electric Co., and Ilford Ltd.: Two papers dealing with the "Osglim" Lamp and its uses for photographic purposes.
ILLUMINATING ENGINEERING SOCIETY (jointly with the Royal Institute of British Architects) (at Royal Society of Arts), at 8.—Discussion on The Lighting of Public Buildings; Scientific Methods and Architectural Requirements. (*a*) An Account of Experimental Work and Results, presented by Dr. E. H. Rayner, J. W. T. Walsh, and H. Buckley. (*b*) Some examples of the Lighting of Decorative Interiors.
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—H. J. E. Peake: Bronze Swords and the Aryan Problem.

WEDNESDAY, MARCH 29.

PREHISTORIC SOCIETY OF EAST ANGLIA (Annual London Meeting) (at Society of Antiquaries), at 2.15.—O. G. Crawford and H. J. E. Peake: A Flint Factory at Newbury Sewerage Outfall Works, Thatcham, Berks.—Miss Nina F. Layard: Presidential Address: Prehistoric Cooking Places in Norfolk, with a brief account of Heating Stones, their History and Significance.—L. A. Armstrong: Further Discoveries of Engraved Flints and Implements at Grimes' Graves.—Dr. A. Smith Woodward: Description of the Rhodesian Skull.—E. J. Wayland: Palæolithic Types of Implements in relation to the Pleistocene Deposits of Uganda.
INDUSTRIAL LEAGUE AND COUNCIL (at Caxton Hall), at 7.30.—Major I. Salmon: The Necessity for Educating the Worker in Industrial Economics.
ROYAL SOCIETY OF ARTS, at 8.—Sir Thomas Oliver: Alcohol in Relation to Industrial Hygiene (Shaw Lecture).

THURSDAY, MARCH 30.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. A. M. Hind: Landscape Etchers: New and Old (1).
CHEMICAL SOCIETY (Annual General Meeting), at 4.30.—Sir James Walker: Presidential Address. At 8—Informal Meeting.
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Prof. H. E. Roaf: The Acidity of Muscle during maintained Contraction.—The late Dr. W. G. Ridewood: Observations on the Skull in foetal specimens of Whales of the Genera *Megaptera* and *Balaenoptera*.—Dr. W. L. Balls: Further Observations on Cell-Wall Structure as seen in Cotton Hairs.—L. T. Hogben and F. R. Winton: The Pigmentary Effector System. I. Reaction of Frog's Melanophores to Pituitary Extracts.—Dr. Agnes Arber: The Development and Morphology of the Leaves of Palms.
NEWCOMEN SOCIETY (at Institute of Marine Engineers), at 5.—Eng.-Comdr. E. C. Smith: The Centenary of Naval Engineering: A Review of the Early History of our Steam Navy.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. H. Mackenzie: Diseases of the Thyroid Gland (Lumleian Lectures), (1).
ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.—Capt. G. de Havilland: Design of a Commercial Aeroplane.
INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—R. B. Matthews: Applications of Electricity to Agriculture.
ROYAL SOCIETY OF MEDICINE (Urology Section), at 8.30.—K. M. Walker: Renal Infections, with an account of experimental work on the ascending route.

FRIDAY, MARCH 31.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—Dr. W. L. Balls: Advantages and Defects of Team Work in Economic Biology.—Dr. F. Kidd: Problems of Fruit Storage.
INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Prof. H. H. Jeffcott: The Milling of Screws, and other Problems in the Theory of Screw-threads.
INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 7.—J. S. Highfield: Presidential Address.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—D. P. Dickinson: The Steel Melting Shop.

SATURDAY, APRIL 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radioactivity (5).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, MARCH 24.

METEOROLOGICAL OFFICE (South Kensington), at 3.—Sir Napier Shaw: The Structure of the Atmosphere and the Meteorology of the Globe (10).
KING'S COLLEGE, at 5.30.—Dr. G. Cook: Some Recent Advances in our Knowledge of the Strength of Materials.

SATURDAY, MARCH 25.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. E. Marion Delf: Science and the Food we Eat.

MONDAY, MARCH 27.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. P. Duval: Données actuelles de la chirurgie intra-thoracique.

TUESDAY, MARCH 28.

UNIVERSITY COLLEGE, at 5.30.—Col. W. M. St. G. Kirke: Imperial Defence as affected by the War (3).

WEDNESDAY, MARCH 29.

HORNIMAN MUSEUM (Forest Hill), at 6.—W. W. Skeat: The Living Past in Britain (10).

THURSDAY, MARCH 30.

SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. L. D. Barnett: The Hindu Culture of India (5).
ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—H. E. Stilgoe: Water (2), Its Distribution and Use (Chadwick Public Lectures).

SATURDAY, APRIL 1.

POLYTECHNIC (Regent Street, W.1), at 10.30 A.M.—Prof. H. E. Armstrong: The Wonders and Problems of Food.
HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. W. A. Cunnington: Woman's Sphere in Savage Africa.

Science at the Post Office.

AFFAIRS relating to the technical services under the Post Office have in the past few years been greatly in prominence; indeed, this has been the case since a Select Committee of the House of Commons began in 1912 to investigate the original contract in connection with the Post Office scheme for an Imperial Wireless Chain. The manner and method adopted by the Post Office in handling this scheme have in many ways proved most unfortunate for the State.

More recently, the serious and widespread complaints of the public concerning the quality of the Post Office telephone service led, in the early part of last year, to the appointment of a Select Committee to inquire generally into the situation; the Committee met forthwith and took much evidence from the officials of the Department and also from witnesses representing various public bodies. This evidence was reported to the House of Commons in June last (Report from the Select Committee on the Telephone Service. H.C. 191 of Session 1921): within the past few days the Committee has submitted its recommendations to Parliament, wherein a radical reorganisation of the Post Office is proposed (Report from the Select Committee on the Telephone Service, 1922 [No. 54]).

Since the Select Committee (of 1921) was appointed, particularly by reason of the allegations made by telephone users regarding the inefficiency of the service provided for them—a matter obviously closely connected with the question of the technical qualifications of the engineering staff employed thereon—it follows that those portions of the evidence given before the Select Committee, which deal with the methods adopted by the Post Office in recruiting its staff, are of considerable importance from the point of view of the reforms which should be taken in hand. Among the witnesses appearing before the Committee who dealt with this subject were the present engineer-in-chief and a former engineer-in-chief to the Post Office. The present engineer-in-chief in his evidence indicated the policy the Department is now adopting in the matter of recruiting its engineers, whilst the former engineer-in-chief, who gave evidence on behalf of the London Chamber of Commerce, contrasted the standard in the qualifications accepted by the Post Office from its engineers with that demanded in similar circumstances by the telegraph and telephone authorities in America and in Europe: the comparison tells greatly to the disadvantage of the authorities at St. Martin's-le-Grand. It was pointed out by the latter witness that whereas, from early times, telegraph and telephone administrations in foreign countries have exercised great care in appointing to the engineering grades leading to the superior positions in the technical branch of their undertakings candidates who have a high standard of technical qualifications, on the other hand, in the British Post Office, subordinate officials, who were not properly qualified, have, in many cases, been promoted into responsible positions.

The condition of affairs in relation to the engineering staff of the Post Office, to which allusion was made by the former engineer-in-chief in his evidence, was in no way in the nature of the giving away of official secrets: the unsatisfactory state of affairs prevailing on the staff side of the engineering department of the Post Office has already been brought to public notice by the Select Committee appointed in April 1912, to inquire into the wages and employment of Post Office Servants. This Committee, in dealing with the Engineering Department, reported:

"That it is proposed to recruit the class of Assistant Engineers by competitive examination, one half of the vacancies being offered to Post Office Servants up to the age of 40 in the case of those who have engineering experience, including junior engineers, and 32 in the case of those who have not, and the other half to outside candidates of not more than 24 years of age who have had two years' training in a technical college or in works. . . .

"That the work has become more technical, more complicated and more difficult, and that the age limit of 32 ought rather to be lowered than abolished.

"That there is no justification for reserving a proportion of the vacancies in the Assistant Engineers' Class for clerks in the Engineer-in-Chief's Office.

"That it is undesirable to limit the field of recruitment for the class of Assistant Engineers to those within the Department, and that it is important that 50 per cent. of the vacancies should be filled by young men of wider education and higher engineering attainments than are usual among Post Office Servants." (Report from the Select Committee on Post Office

Servants (Wages and Employment). No. 268. 1913. See para. 776.)

Although, as the above extract from the Select Committee's Report shows, it was tacitly admitted by the officials who gave evidence that the need existed for recruiting for the Post Office service men of wider education than those already serving, nevertheless a scheme, introduced in 1907, for recruiting twenty-five per cent. of engineers by open competition has been allowed to remain in abeyance from 1911 until the present time. Now that engineering vacancies are again to be filled by open competition from among candidates who have received an adequate education, twenty per cent. only of the engineers required for the telegraph and telephone services are apparently to be recruited in this way, whilst the remaining eighty per cent. of these positions are to be reserved for the subordinate grades serving in the Department, in order to fill these as heretofore by internal promotion.

In the matter of recruiting their engineering staff, the attitude of the British Post Office has been widely different from that of the telegraph and telephone administrations in other parts of the world. In the early days of telegraphy, when the specialised technical education needed by the telegraph engineer was not provided in the then existing schools, the telegraph administration itself, in many cases, arranged for appropriate courses to be given under its own auspices, as for example the courses at the East Indian Engineering College, Cooper's Hill; at the École Supérieure des Télégraphes, Paris; at the Istituto superiore, Rome; at the State Telegraph School, Stockholm; at the Versuchsamt, Berlin; etc. Now that instruction of a suitable kind is available in the technical high schools and universities abroad, foreign telegraph and telephone administrations, in practically every part of the world, recruit their engineers from amongst men who hold a diploma in civil or mining engineering as well as some recognised certificate in electrical engineering, or a diploma in electrical engineering; and, in some cases, where suitable courses are provided at universities, as in Belgium, Bavaria, Germany, etc., candidates for the higher career on the technical side are required to possess either a suitable degree or to hold a recognised diploma of equivalent standard.

Quite apart from the fact that the telegraph and telephone services cannot be carried on satisfactorily in this country by engineers possessing a lower standard of qualifications than that demanded from men occupying similar positions in foreign countries, it is exceedingly important on other grounds that the recruitment of engineers for the Post Office engineering department shall, now that a complete re-organisation of the Department is recommended by a Select Committee, be placed upon a sound basis. How important the other grounds are will readily be apparent if the estimates presented to Parliament last year be scanned through, for it will be found that the "establishment" of Post Office engineers is in this document shown to be above 570.

A further matter which, in view of the complicated nature of the engineering work undertaken by the Post Office and of the responsibilities of those in high positions, requires early attention is the status and method of selection of the chief of the Post Office engineering department and his immediate assistants. From every point of view, it is imperative that the officials holding these positions should be men of eminence in the engineering profession. Strong reasons exist at the present time for throwing open these appointments to the engineering profession generally. The adoption of such a course would present no difficulties, nor would it be exceptional: the appointment of the head of a department has at all times been recognised as being one which may be filled by a candidate from outside the Department. Many precedents exist in the Civil Service for the bringing in of a person from the outside to fill vacancies in high positions: for example, in the Post Office itself, during the past twenty-five years, four of the five men who have held the chief administrative position, that of secretary, and one of the engineers-in-chief have been persons who began their careers and spent many years outside the Department. It cannot be questioned that the chief technical adviser in an undertaking of the magnitude and complexity of the Post Office telegraph and telephone department requires to be a man of professional attainments of as high an order as is the administrative chief whose colleague he is to be.

No difficulty need be experienced by the Postmaster General in making a suitable selection of a technical adviser from an open field of candidates, if he will but call in the assistance of an *ad hoc* committee or board to advise him as to the merits of the several candidates; such a committee or board might, for his purposes, consist of the presidents of the Royal Society, the Institution of Civil Engineers and the Institution of Electrical Engineers. It has for some time been widely felt that such a method of filling the chief positions in government departments has become generally necessary in order to meet the present-day conditions. So far as the Post Office is concerned, in view of the announcements which have appeared that the present engineer-in-chief will be vacating his position in May next, the matter has become pressing. The adoption of the procedure indicated by the Postmaster General, when filling this vacancy, would meet with very general approval and give considerable satisfaction in the country.

The Imperial Institute.

It is astonishing that, at a time when the Imperial Institute is looking forward to further developments in its work, a proposal should be put forward involving the dismantling of more than half of the recently extended and improved collections in the Public Exhibition Galleries of the Institute—without question the finest illustration of economic geography in the world—in order to make room for the war relics known as the Imperial War Museum at present housed in the Crystal Palace. The *Times* of March 7 contains leading and special articles on the subject in which a clear case is made for the abandonment of the proposal. Attention is directed to the resolution of protest recently passed by the Executive Council of the Institute. While appreciating the desire for economy in housing the War Museum, the council considers that this object should be achieved by some other method than by a plan which would be seriously detrimental to the development of the educational and commercial work for which the Imperial Institute was erected and endowed. Resolutions of protest have also been received by the council from a number of important bodies, including the Association of British Chambers of Commerce; the Chambers of Commerce of Liverpool, Manchester, Glasgow, and Bristol; the Royal Institute of British Architects; the Timber Trade Federation; the Institute of Builders; and the Silk Association.

For a quarter of a century the Imperial Institute with very slender means has been carrying on work of great service to the Empire, a fact far too little known and appreciated. The reward of such endeavour should be the provision of better facilities for development, and it is precisely in this respect that the proposals now put forward on behalf of the War Museum would be so detrimental in their effects. The Imperial Institute is becoming the recognised headquarters of organised effort in this country for the development of knowledge of the natural resources of the overseas countries of the Empire, and it is to be hoped that the Government will see that nothing of the character of the proposals justly condemned by the *Times* shall prevent the achievement of so desirable a purpose.

A Treatise on Petroleum.

Petroleum. By Sir Boverton Redwood. Fourth edition, reset throughout. In three Volumes: Vol. 1, pp. xxx+364+pl. 16. Vol. 2, pp. iv+365-740+pl. 17-31. Vol. 3, pp. iv+741-1353. (London: C. Griffin & Co., Ltd., 1922.) £5, 5*s*. net.

In a review of the first edition of this work, published in Nature in December 1896 (vol. 55, p. 169), it was asserted that "to write, or to compile a comprehensive text-book on petroleum, demands an acquaintance with dissimilar subjects and varying walks of life, very rarely centred in one individual. The present work is and will ever remain remarkable as the production of a man whose scientific attainments, and whose relation to the petroleum industries, were such that he, probably better than any other living man, was fitted to undertake the task."

During the quarter of a century that has since elapsed the "dissimilar" sciences that form the foundation of petroleum technology have both widened and deepened; chemical research has extended our knowledge of the constitution of the hydrocarbons that form mineral oil; the newly developed branch of colloidal chemistry, in its bearing on the properties of argillaceous substances, has affected the methods of refining and thrown new light on the problems of crude-oil migration underground; the discovery of new occurrences and, especially, the compilation of data obtained from established fields have put a new complexion on the questions of oil geology; improvements in mechanical engineering have modified the methods of exploitation and transport; whilst the remarkable development in the use of internal combustion engines, inspired by stern necessity during the war, has been accompanied by an extension of the theoretical and practical aspects of oil as a source of power. In complexity and volume each of these phases of the natural history of oil and the technique of its uses is to-day comparable to the whole range of petroleum technology as it was when Sir Boverton Redwood first attempted the task of summarising the disconnected and apparently unrelated data of the petroleum industry.

To keep in touch with these developments was perhaps possible to the author if to no one else; to keep abreast of them he frankly recognised as impossible, and thus we find in this new edition of a work which "is and will ever remain remarkable" the results of the friendly co-operation of more than two dozen specialists. The contributory work of these friends is evidence of their belief in the value of this treatise as a work of reference, and is at the same time a sign of the magnetic personality of the author and the affectionate respect with which he was regarded among all classes of workers in the oil world. But the thorough revision of some parts in this way serves to bring into relief others which remain as they were issued with the third edition in 1913. The book in this respect bears the marks of the war, during which the author's unremitting devotion to honorary public service left him insufficient time for his accustomed methodical compilation of new facts and for the judicial examination of new theories. To specialists in the accessory sciences and to local workers in distant fields, who will necessarily subject appropriate

chapters to microscopic analysis, the deficiencies thus left will be obvious; to those who knew the author personally, and were thus able to estimate the heavy burdens which were laid on him during the anxious years 1914–18, these blemishes will be regarded as veritable war wounds.

Thus, this fourth edition of a recognised standard work, even with its blemishes, will be to workers in the oil world an appropriate memorial to its author. In most chapters there are the results of his characteristically painstaking assembly of data; the constant sense of relativity shown in their summary; the judicial instinct with which conflicting theories are balanced; the conscientious recognition of the work of others; the cautious estimates of "prospects" likely to affect commercial interests; the record of observations privately obtained from innumerable friends; and, finally, the signs of war weariness which probably brought about the fatal illness to which he succumbed only two days after passing for press the complicated section on shale oil and allied industries.

The publication of this edition marks a definite stage in the history of petroleum technology; in complexity its ramifications have now passed beyond the comprehension of any one individual; no single person can hope to prepare the fifth edition of Redwood's "Treatise." Its author has passed away, but his spirit remains incarnated in the Institution of Petroleum Technologists which he founded just before the war, and that body might well regard as its chief mission the maintenance up to date of this its bible as a standard work of reference. The Institution has already in the press a volume summarising recent developments in special branches of the petroleum industry, and this work, supplemented by Mr. Dalton's revised and extended bibliography, will bridge many of the gaps left in the Treatise by Sir Boverton Redwood's unexpectedly sudden death.

T. H. HOLLAND.

Entropy as a Tangible Conception.

Entropy as a Tangible Conception: An Elementary Treatise on the Physical Aspects of Heat, Entropy, and Thermal Inertia for Designers, Students, and Engineers, and particularly for Users of Steam and Steam Charts. By Eng. Lt.-Commr. S. G. Wheeler. Pp. 76. (London: Crosby Lockwood and Son, 1921.) 8*s*. 6*d*. net.

OPINIONS will differ as to the merits of the title which Lt.-Commr. Wheeler has chosen for this volume. The extreme relativist, who regards the notion of force derived from our muscular sensations as a relic of animism, will no doubt condemn it. "To-day we have dispossessed the demons, but the *ghost of a muscular pull* still holds the planets in place."[1] On the other hand, the student of either physics or engineering will welcome any suggestion which assists him in understanding the nature of the "ghostly quantity," entropy. "The more shadowy the conception to be visualised, the greater the need of a definite material analogy." The quotation is from the instructive presidential address to the Physical Society of London delivered by Prof. Callendar in 1911. Here it is pointed out that the caloric theory is perfectly consistent with Carnot's principle and with the mechanical theory for all reversible processes. The quantity measured in an ordinary calorimetric experiment is the motive power or energy of the caloric, and not the caloric itself. Prof. Callendar identifies caloric with the "thermodynamic function" of Rankine, or the "entropy" of Clausius.

With this address and with the important paper by Sir J. Larmor "On the Nature of Heat" (Proc. Roy. Soc. vol. 94, p. 326, 1918) we imagine Lt.-Commr. Wheeler is not acquainted. He sets out to give a more tangible interpretation of entropy than that afforded by Boltzmann's statement that it is "the logarithm of the probability of a complexion." This he endeavours to do, and in our opinion with considerable success, by means of mechanical analogies. There is, needless to say, nothing novel in such an attempt. Poynting and Thomson, in their text-book on "Heat," direct attention to quantities which are analogous to entropy; indeed, we may, according to Prof. Callendar, go back to "the old picturesque phraseology of the material fluid, implied in Carnot's waterfall." Just as gravitational energy may be regarded as the product of mass and the height of the mass above zero level, so heat energy may be regarded as the product of "thermal inertia" and temperature. Thus entropy, being, as Swinburne called it, "the measure of the incurred waste," may be interpreted as "incurred thermal inertia." But in this book a distinct point, which we had not previously met with in print, is made by considering, not linear, but rotational, motion, so that thermal inertia corresponds to the moment of inertia, mk^2, of a rotating system. Here we have a case where the rotational inertia is capable of variation through changes in the value of k, the radius of gyration.

This may be illustrated by suspending a flat, circular disc from a point in its circumference by a thin wire by means of which it can be spun round around a vertical axis (Fig. 1). At first the disc will rotate about its original vertical diameter, but on the attainment of a certain speed the disc will start to

[1] Dr. Mott-Smith, in J. M. Bird's "Relativity and Gravitation." (Methuen, 1921.)

rise, the wire now making an angle with the vertical whilst the disc rotates about an axis through its centre and perpendicular to its plane, the centre remaining vertically below the fixed point of suspension. At a still higher speed the disc will begin to whirl about the point of suspension with the wire and its own plane both practically horizontal. "The changes in inertia of the rotating disc occur at definite speeds as it receives energy, and it is not so improbable as at first sight it may seem, therefore, that the changes in form which occur at perfectly definite temperatures (as, for instance, when heat is added to ice to turn it to water, and to water to turn it to steam) may really take place in a similar manner by some corresponding change in disposition in the particular internal or ionic movement which we imagine to constitute heat; in other words, that this motion may enjoy some form of increased freedom which may be regarded as an increase of thermal inertia."

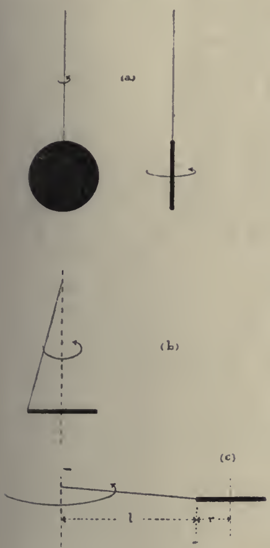

FIG. 1.—An instance of change in rotational inertia.

The conception of entropy as incurred thermal inertia is worked out in detail in the later chapters, and an interesting mechanism is described which affords a parallel to the behaviour of the working substance in an engine (Fig. 2). In this model the actual working substance is represented by an arrangement consisting of a short shaft carrying a pair of heavy "governor" balls mounted on bell-crank levers controlled by varying tension springs. Changes in the rotational inertia of the revolving masses represent changes in the thermal inertia of the working substance. With the apparatus illustrated in the book it is possible to go through a cycle of operations, such as the usual steam-engine cycle (Rankine's cycle) or Carnot's cycle, and examine the analogies between thermal and mechanical processes in detail. Teachers and students of thermodynamics would be well advised to study this volume.

In connection with such mechanical analogies our attention has been directed to an address delivered before the Institution of Civil Engineers in 1883 by Prof. Osborne Reynolds. The lecturer referred to the work of Rankine, who assumed the thermal motion to be rotatory, and, when compelled to abandon the theory of "molecular vortices," called on all those who taught the subject of thermodynamics to try to find some popular means of illustrating the second law. "The call was made twenty years ago; but I believe up to the present no such illustration has been forthcoming." "The communication of heat to matter means the communication of internal agitation—mob agitation. If, then, we are to make a machine to act the part of hot matter, we must make a machine to perform its work in virtue of internal promiscuous motion amongst its parts." As an illustration, Osborne Reynolds instances the possibility of raising a bucket by violently shaking the upper end of a heavy rope or chain. A modification of the illustration is afforded by a kind of chain composed of a series of parallel horizontal bars of wood connected and suspended by two strings. "By giving a circular oscillation to the upper bar, the whole apparatus is set into a twisting motion (agitation); the strings are continually bent, and the vertical length of the whole system is shortened." Osborne Reynolds refers also to the governor of a steam-engine, which acts by kinetic elasticity depending on the speed. "The motion of the governor is not of the form of promiscuous agitation, but, though systematic, all the motion is at right angles

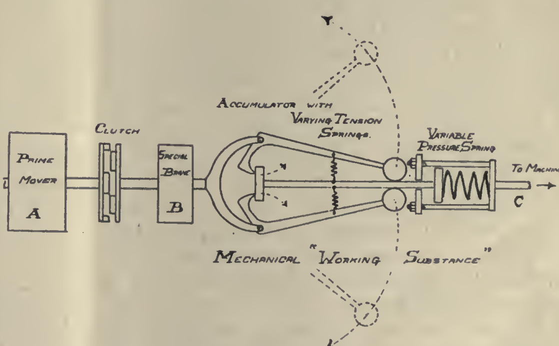

FIG. 2.—Mechanism illustrating the behaviour of the working substance in an engine.

to the direction of operation, so that the principle of its action is the same." Here we have the germ of the model discussed in the book under review. We may venture the opinion that the development of this model owes not a little to the late Prof. A. M.

Worthington, whose name, however, is nowhere mentioned. "These kinetic examples of the action of heat must not be expected to simplify the theory, except in so far as they give the mind something definite to grasp; what they do is to substitute something we can see for what we can barely conceive."

The Mass Formula of Cathode-ray Corpuscles.

Vérification expérimentale de la formule de Lorentz-Einstein. Par Prof. Ch.-Eug. Guye, en collaboration successive avec S. Ratnowsky et Ch. Lavanchy. (Mémoires de la Société de Physique et d'Histoire naturelle de Genève, vol. 39, fasc. 6.) Pp. 273–364 + plates 4–6. (Genève: Muséum d'Histoire naturelle, 1921.) 20 francs.

THIS memoir gives a detailed account of experiments made by MM. Guye and Ratnowsky in 1907–9, and by MM. Guye and Lavanchy in 1911–13, with the object of testing the mass-formulæ of Abraham and of Lorentz for the cathode-ray corpuscles. Preliminary notices of these researches have appeared from time to time, but now they are published in their final form, preceded by a theoretical and historical introduction of twenty pages, whilst twenty pages are devoted to the experiments of Guye and Ratnowsky, and forty pages to those of Guye and Lavanchy; the whole concludes with a small collection of tables and plates. There are records of twenty-seven experiments by Guye and Ratnowsky for the range from $\beta = 0{\cdot}21$ to $\beta = 0{\cdot}59$, and of 151 experiments by Guye and Lavanchy from $\beta = 0{\cdot}25$ to $\beta = 0{\cdot}49$. The first series of experiments gives for the excess of the observed mass of the electron above the Lorentz mass a mean value of five thousandths, and for that above the Abraham mass a mean value of nineteen thousandths, with a probable error of about three thousandths; the second gives for the same quantities two ten-thousandths, eleven thousandths, and one two-thousandth respectively. Thus the evidence of these investigations is strongly in favour of the Lorentz mass formula, in complete agreement with previous researches of similar rank, such as those of Bucherer, Wolz, and Neumann on β-rays, and of Hupka on accelerated photo-electrons.

Like Hupka, Guye and his associates used a relative method; the electric or magnetic force, as the case happened to be, which was required in order to produce a prescribed deflection of a given fast cathode-ray pencil, was compared with that needed to produce an equal deflection of a slow cathode-ray pencil selected as a standard. But whilst Hupka used only the magnetic deflection and relied for the determination of the speed of his photo-electrons on the measurement of the vacuum tube potential employed in accelerating them, Guye and his associates used both the electrostatic and magnetic deflections, not simultaneously, as had been the usual previous practice, but separately and alternately. Thus they eliminated errors due to variations in the state of the vacuum tube, rejecting *ab initio* all experiments in which sudden changes in its condition were suspected. They avoided the large errors which are almost inseparable from the measurement of very high potentials (of the order of 80,000 volts), which completely vitiated Hupka's results, at any rate according to Heil's criticism of his experiments.

The relative method, or method of "identical trajectories," as Guye and his associates call it, has the advantage of not requiring an exact knowledge of the distribution of the electric and magnetic forces, which, especially for the electric field, is very difficult to determine with sufficient accuracy. Since the speed of an electron is not altered by a magnetic field, we can for two cathode-ray pencils of different speeds make the terminal deflections equal by a proper choice of the ratio of the magnetic forces at corresponding points, and so ensure that the trajectories are identical throughout; then the electro-magnetic momenta (transverse mass × speed) will be in the ratio of the magnetic forces—*i.e.* of the electric currents generating the field. But for the electric field the equality of the terminal deflections of two cathode-ray pencils of widely different speeds does not guarantee the identity of their trajectories, if only because the electric field generally alters the speed. In the experiments of Guye and his associates the changes of speed produced amounted to only a few thousandths of the whole, so that the trajectories were very nearly identical, and the error arising from this cause was negligible. Consequently for two cathode-ray pencils of widely different speeds undergoing equal electrostatic deflections the products of their transverse masses into the squares of their speeds could be taken to be in the ratio of the deflecting electric forces—*i.e.* of the differences of the potential between the plates of the condenser used to produce the deflection. Thus the ratios of the speeds and of the transverse masses of the two cathode-ray pencils could be expressed in terms of the measured ratios of the currents in the magnetising coils and the potential differences of the condenser. In this way the speeds and masses of a number of cathode-ray pencils of various high speeds were compared with those of a pencil of a standard low speed, without the need of finding the distribution of the electric or magnetic fields or the discharge potentials for the high-speed pencils.

In order to test the mass formulæ the speed and mass of the slow-speed pencil were found by measuring the discharge potential directly with an electrometer, which could be effected with sufficient accuracy, because in this case the difference of potential was only about 14,000 volts. The speed ($\beta = 0{\cdot}228$) was calculated by successive approximation, the appropriate mass formula being employed to estimate the necessary correction to the zero mass, which for this low speed amounted to only 3 per cent. The result, together with the measured electrostatic deflection, supplied the data needed for the evaluation of the electric field integral, which was used in the comparison with the high-speed cathode-ray pencils. In the earlier experiments this field integral was also evaluated by graphic calculation from the constants of the condenser, but the experimental method of determination was adopted finally as more accurate, the difference between the two methods being about 5 per cent. In the later experiments curved condenser plates were used, in order to render the trajectories more nearly equipotential; in this case graphic calculation was impossible. No data are given for the magnetic field integral, perhaps because it was always eliminated; nevertheless, its evaluation from the constants of the apparatus might have been useful as a check, and would have made the direct calculation of the magnetic deflection possible, with a view to meeting beforehand Heil's objection to Hupka's use of the relative method, viz. that the observed magnetic deflections differed widely from those calculated from the measured currents and the constants of the apparatus.

Apart from the absence of this check, every precaution seems to have been taken to ensure accuracy; the earth's magnetic field was compensated, electrostatic influences were guarded against, special arrangements were used to secure regular working of the vacuum tube, and the number of observations was amply sufficient to eliminate practically all accidental errors. The authors are to be congratulated on producing a most valuable contribution to our knowledge of the dynamics of the electron.

British University Problems.

Second Congress of the Universities of the Empire, 1921: *Report of Proceedings*. Edited by Dr. Alex. Hill. Pp. liv+452. (London: Published for the Universities Bureau of the British Empire by G. Bell and Sons, Ltd., 1921.) 21*s*. net.

THE Report of the Proceedings of the Second Congress of the Universities of the Empire held at Oxford on July 5–8, 1921, has just been published as a volume of more than five hundred pages. It will be recalled that the first of these Congresses was held in 1912, and, but for the intervention of the war, would have been followed by the second in 1917. Fifty-nine universities—six more than in 1912—sent upwards of three hundred delegates and representatives to it. The main topics under discussion were the balance of studies; the teaching of civics, politics, and social economics; secondary education; adult education; technological education; the training for commerce, industry, and administration; the training of school teachers; finance; research; and the interchange of teachers and students—all, of course, with reference to the universities. Such a varied and comprehensive programme required some skill in arranging and handling, and Dr. Hill is to be congratulated on the way he has edited the Report.

Thirty-five papers were presented to the Congress. These have been printed *in extenso*, together with verbatim records of the discussions which followed. Though lack of space prevents it, a mere list of the names of the various speakers would be interesting in itself, as giving a list of distinguished scholars drawn from all quarters of the British Empire. For such particulars, reference must be made to the Report itself. The opening address was given by Lord Curzon, the Chancellor of the University of Oxford, who welcomed the Congress to Oxford, and expressed his opinion of the value of such Congresses as having it in their "power to play a very important part in developing the organisation and drawing closer the bonds of the British Empire." This was followed by an able paper on "The Present and the Future of Hellenism." Unfortunately, the discussion was limited, no doubt, by the fact that it was followed by four other papers in immediate succession. Sir A. J. Balfour, the Chancellor of the Universities of Cambridge and Edinburgh, who presided at the discussion on "The Universities and the Teaching of Civics, Politics, and Social Economics," in his opening speech raised the question of innate differences of races among human beings, but decided, very wisely, not "to wander into a topic so tremendous." In the general discussion, the point that "only a few boys in any school can go to the university" was raised, and, curiously enough, was emphasised in a paper which followed dealing with the question of the university and secondary education. The same point came up in another form, when Lord Haldane, in a notable address on adult education, referred to the extent to which the universities were dependent on the taxes and rates. "Democracy," he said, "is beginning to ask why it is that, while they pay the rates and taxes, only a limited section of society gets

the benefit." A most interesting discussion followed the six papers dealing with various aspects of this subject.

On the subject of technological education, four papers were contributed. Lord Crewe deprecated "the intellectual vulgarity that sets the scholar in a different class from the workers, either for laudation or contempt." In the discussion, reference was made to the "great misfortune" of segregating students of technology in separate "technological universities," and so preventing them from mixing with the students of other faculties, to their mutual loss. In the debate on "The Universities and the Training of School Teachers" a similar note was struck, several speakers emphasising the necessity of a university atmosphere for such training.

Sir Robert Stout, Chancellor of the University of New Zealand, in opening the meeting on "University Finance," gave an interesting account of educational finance in New Zealand. The discussion, *inter alia*, brought into relief the different attitudes of the over-seas universities and the home universities to the question of State aid and university autonomy. One of the most important, and certainly one of the most interesting, discussions took place on the subject of "Research." Lord Robert Cecil, in summing up the debate, made it quite clear that at present research in the universities is mainly obstructed by "want of money and want of leisure." In this we may well agree. In the last session, the case for the institution of a Sabbatical year for the professoriate was well argued, but obviously "want of money" is the rock upon which such a scheme will founder. Sympathetic references which were made to the death of Lord Balfour of Burleigh, who should have presided at the discussion on "The Training for Commerce, Industry, and Administration," are duly recorded.

The Report gives a full account of a most instructive congress, and the papers and discussions bristle with points which in recent years have been giving rise to much thinking in university circles. Any one interested in higher education cannot fail to profit by reading it.

India as a Centre of Anthropological Inquiry.

Principles and Methods of Physical Anthropology. By Rai Bahadur Sarat Chandra Roy. (Patna University Readership Lectures, 1920.) Pp. xiii + 181. (Patna: Government Printing Office, 1920.) 5 rupees.

THERE is not an anthropologist in Europe who will not extend a welcome to this work by Rai Bahadur Sarat Chandra Roy, reader in anthropology at Patna University, not only for what it is, but also for what its appearance signifies. Anthropology, hitherto a plant of exotic growth in India, has at length taken root in the native mind. A single readership in a single university is a somewhat slender root for a plant which has to cover more than 300 millions of people, but those who have noted the series of excellent researches and monographs which have been published in recent years by Mr. Roy and by his colleagues and disciples will have no fear of the result if a fostering hand be extended by the Government of India. Our knowledge of the peoples of India has been laid by those great-minded Civil Servants who realised that good government must be based on accurate, intimate, and sympathetic records of the mentality, customs, and traditions of the governed. It was at the feet of one of these great Indian servants, Sir Edward Gait, now chancellor of Patna University, that Mr. Roy was introduced to the methods and aims of modern anthropology.

The book under review, "Principles and Methods of Physical Anthropology," is based on the first course of lectures given by Mr. Roy as reader in anthropology in Patna University. The lectures now published, six in number, form one of the best introductions to the study of anthropology in the English language. It is true that many minor statements require emendation or qualification, but we are surprised that one who has made his reputation as a cultural anthropologist should have grasped so accurately the methods, aims, and theories of those who study the evolution of the human body and brain, as well as the rise and spread of modern races of mankind.

A mere enumeration of the titles given to the six lectures or sections into which this book is divided will show the scope of the author's work. The first is devoted to the evidence relating to man's place in the zoological scale; the second to the evidence relating to man's antiquity; the third to the theory of evolution; the fourth to the theory of evolution applied to man's body, brain, and culture; the fifth to man's first home and early migrations; the sixth to the evolution of human races and their classification. Thereafter follow appendices giving the chief schemes for classification of human races, bibliographies, etc.

Hitherto the problems of anthropology have been viewed solely through European eyes; it is well that they should be seen also from the point of view of those who live on the banks of the Ganges. Certain it is that India is nearer the hub of the anthropological universe than Western Europe. Many anthropologists in looking round the world for the most likely place to serve as a cradle land of mankind have selected India or some neighbouring region—a belief in which Mr.

Roy has faith. But whether this be so or not there can be no doubt that India lies on the great racial divide of modern mankind. Within its population taper off the three great divisions into which human races are grouped—the white, yellow, and black. Here, too, three great linguistic families come into juxtaposition. It is a vast treasure-house of ancient rites, beliefs, and customs.

It is a great task to which the author of this work has set his hand. He is bold enough to hope that his school will do for the 300 millions of India what the anthropological schools of Cambridge and Oxford have done for the 36 millions of England. The English pioneers had an uphill fight, and it is the memory of this experience which will make them extend a willing and helping hand to Rai Bahadur Sarat Chandra Roy, reader in anthropology in Patna University, in the difficulties and apathy which now confront him and his school.

Arthur Keith.

Our Bookshelf.

University of London. Galton Laboratory for National Eugenics: Eugenics Laboratory Memoirs, VII. On the Relationship of Condition of the Teeth in Children to Factors of Health and Home Environment. By E. C. Rhodes. Pp. viii + 80. (London: Cambridge University Press, 1921.) 9*s.* net.

Mr. Rhodes has analysed the records of five School Medical inspectors charged with the examination of the school children of an administrative county, with a view of discovering whether relationship could be traced between condition of teeth and factors of health and home environment. The bulk of the paper is devoted to an investigation of methods of standardisation, *i.e.* to the solution of a problem of the following kind: given that two observers having different standards of classification examine and group into classes random samples of the same population, required, the corrections of the several distributions needed to render the results comparable. Two methods of solution, involving different assumptions, are employed. It is shown that the individual variations of standard are very large and that, for purposes of correlation, it is necessary to deal separately with each inspector's data. Actually very little correlation was found between the state of caries in the teeth of children aged 12-14 and either general health or home environment.

Both the author and Prof. Karl Pearson, in an introductory note, emphasise the need of standardisation. The results of this inquiry justify the following remark of Prof. Pearson: "There are many urgent practical problems which could be adequately solved by a study of the child population of this country, but they can only be solved by the leisurely laboratory method of observation, by standardised judgments and an efficient training in modern statistical methods. At present the observations are too rapid to be of great scientific value, the judgments are personal opinions rather than real measures of fact, and the statistical methods of school officers' reports rarely indicate a knowledge extending beyond the elementary rules of arithmetic. These results are not due to any fault of the medical officers themselves, but to the inadequate system under which they are trained for their work, and to the speed under which they are compelled to form their record."

Mr. Rhodes' paper, despite the necessarily negative character of his main conclusions, is a valuable piece of work and enforces lessons which the public, not excluding medical officers, are slow to learn.

Hellenism and Christianity. By Edwyn Bevan. Pp. 275. (London: George Allen and Unwin, Ltd., 1921.) 12*s.* 6*d.* net.

With the exception of two essays on "Bacchylides" and on "The Greek Anthology," all the essays in this volume deal with some aspect or other of the relationship of Christianity to the world, ancient or modern. Touching the ancient world, there are two essays on the earliest contacts of Christianity and Paganism, and two especially delightful ones on St. Augustine. The essays on the modern world all revolve around the conflict between our "rationalistic" civilisation and religious experience as focussed by the life and teaching of Christ. The author's limpid style makes it a pure pleasure to read his arguments, and his complete candour should secure for them respectful consideration even from those who stand intellectually aloof from theology. A good example of his method, on a non-controversial topic, is the short essay on "Dirt," in which he works out in a most interesting way the polarity of our feelings towards objects, like our bodies and sex, which we treat as at once sacred and unclean. Of miracles he holds that their possibility cannot be scientifically disproved, but at the same time he regards them as altogether "peripheral" in Christian belief, and he finds the evidence both for the Virgin Birth and for the Bodily Resurrection of Christ too uncertain to build the edifice of faith upon them.

The intellectual difficulties of the Christian faith arise no longer from any supposed conflict with natural science—evolution is accepted by "educated Christian opinion" and the Book of Genesis is mythology—but with anthropology, comparative psychology, and philosophy. At most, however, these can show only, not that the Christian hypothesis is *impossible*, but that it is *unnecessary*. Mr. Bevan's answer is that the case for Christianity rests, not on argument, but on the quality of the Christian life. "If the Church Christian wants to convince the world of the supreme value of its ideal of love, it can only do so by steadily confronting the world with the actual thing." True, but this only means that among all the millions of nominal Christians, Christianity has rarely been seriously tried. Will it ever be widely tried? That is the question.

R. F. A. H.

Hermann v. Helmholtz' Schriften zur Erkenntnistheorie. Herausgegeben und erläutert von P. Hertz und M. Schlick. Pp. x + 175. (Berlin: Julius Springer, 1921.) 90 m.

The centenary of Helmholtz's birth is the occasion of the publication of these little known writings. They are chosen for their special importance in regard to present-day problems and in particular to the recent developments of mathematical theory.

The Historical Geography of the Wealden Iron Industry. By M. C. Delany. (Historico-Geographical Monographs.) Pp. 62+3 maps. (London: Benn Brothers, Ltd., 1921.) 4s. 6d. net.

THIS is the first of a series of "historico-geographical" monographs published under the editorship of Prof. H. J. Fleure, which are to be essentially research monographs. It would greatly enhance the value of the series if in future numbers the matter were indexed or at least paragraphed with suitable headings. A single chapter of forty pages does not facilitate reference. As regards its matter, however, this short monograph is well done, although it is difficult to follow the distribution of the Wealden forest at different ages on the sketch maps provided. The author traces the iron industry in this part of England from its beginning, in Roman days or earlier, to its decline in the eighteenth century, when, as is well known, it could no longer compete with the more favourably located industry on the coal-fields. There appears to be a gap in the history of the industry for seven or eight centuries after Roman times; at any rate, the author has been unable to find evidence of its existence in that period. Some interesting details are given of the methods employed and the kind of iron work produced.

Letters to the Editor.

Precursors of Wireless Telegraphy.

A TRADITION is growing (cf. NATURE, March 9, p. 316), and requires scrutiny, that it was owing to discouragement by Sir George Stokes that D. E. Hughes abandoned his experiments in 1879, anticipatory of the methods and apparatus of modern wireless telegraphy. This is in contrast to all that is known of Stokes' extreme caution in advancing opinions, for which in fact he has usually been blamed, for example by Kelvin and Rayleigh in connection with spectrum analysis. From the modest letter of Hughes published in the *Electrician* in 1899, and in Fahie's "History of Wireless Telegraphy," Appendix D, which describes his very remarkable investigations, such an inference could scarcely be fairly drawn: "The experiments shown were most successful, and at first they (Spottiswoode, Huxley, and Stokes) seemed astonished at the results; but towards the close of three hours' experiments Prof. Stokes said that all the results could be explained by known electro-magnetic induction effects, and therefore he could not accept my view of actual aëreal electric waves, unknown up to that time, but thought I had quite enough original matter to form a paper on the subject to be read at the Royal Society." Hughes continues that he was so dismayed at being unable to convince them that he actually refused to write a paper on the subject until he was better prepared to demonstrate the existence of these waves, and with this end in view he continued his experiments for some years (Fahie, *loc. cit.* p. 310).

The key to the matter has, I believe, been supplied by the extracts from Hughes' original notebooks, now in the British Museum, which Mr. Campbell Swinton read at the Jubilee Meeting of the Institution of Electrical Engineers, and which he has kindly shown to me in manuscript. They show that Hughes held that in some way "the effects were due to electric conduction through the air" (NATURE, *loc. cit.* p. 316). Those who knew Stokes would expect that he would demur stoutly to such a doctrine as misleading, and would insist that "they could be explained by known electro-magnetic induction effects." For it was not unknown even before Maxwell's theory (1860–64) that the inertia of such induction could propagate waves along wires, which, if of very high frequency, would travel, as Kirchhoff showed in 1857, with the speed of light. The transcendent advance of Maxwell's definite theory, confirmed as fact by Hertz in 1886–1888, was that in favourable conditions such waves could release themselves from the matter and travel free across space; and, more fundamental still, that it is just by such free transmission that all electric and optical effects become established.

It seems clear to my mind that the affair was a misunderstanding, such as can readily be imagined, between the tenacity of the practical inventor and the insight of the theorist who was conscientiously determined not to give countenance to a misapprehension of the nature of the phenomena. But if Maxwell had been present (he had recently died), or Kelvin, who were more closely interested in the problem of the nature of the transmission of electric influence than Stokes, they would perhaps have used further efforts not to allow the subject to drop; though it would at that time have required all the resources of theory to make progress along the lines of these experiments.

The episode is so interesting from the point of view of the philosophy of history of scientific discovery, not to mention the practical application of the microphone operating by loose contacts by Hughes himself, in the manner developed much later by Branly and Lodge and Marconi, that a full statement from all aspects should be on record.

JOSEPH LARMOR.

Cambridge, March 18.

Stonehenge: Concerning the Four Stations.

JUST within the surrounding earthwork of Stonehenge there are two stones symmetrically placed with reference to each other on opposite sides of the centre. There are also two mounds in corresponding complementary (or reversed) positions. The arrangement is shown on the accompanying plan (Fig. 1), the dimensions for which have been taken from Flinders Petrie's very careful measurements as published in his work, "Stonehenge — Plans, Description and Theories" (1880).

For the purpose of this paper the arrangement is referred to as "The Four Stations." The two stones are numbered respectively (on Petrie's system) 91 and 93, and the two mounds 92 and 94.

Concerning this pair of stones and pair of mounds Colt Hoare remarks:—

> "There are two small stones within the *vallum*, and adjoining it, whose uses have never been satisfactorily defined. The one on the south-east side is near nine feet high, and has fallen from its base backwards on the *vallum*; the other, on the north-west side, is not quite four feet high; both rude and unhewn. There are also two small *tumuli* ditched round, so as to resemble excavations, adjoining the *agger*; they are very slightly elevated above the surface, and deserve particular notice, as they may give rise to some curious and not improbable conjectures" ("Ancient Wilts," i. p. 144).

Colt Hoare opened the northern mound (No. 94), and in it found "a simple interment of burned bones." He also opened the southern mound (No. 92), "but found nothing in it" ("Ancient Wilts, i. pp. 144 and 145).

From the fact that a cremated interment has been found in mound No. 94 it has been assumed that both the mounds are barrows, and that they are moreover of the same period as the Round Barrows in the neighbourhood. On this assumption it is concluded that Stonehenge was constructed during the Bronze Age period or perhaps later. The arguments for this conclusion may be briefly summarised as follows :—

(*a*) In mound No. 94 was found a cremated interment.

The two mounds are therefore barrows, and are of Bronze Age date.

(*b*) As barrows they would originally have been isolated constructions of circular bowl-shaped form. This [supposed] original form has been partly infringed upon by the bank of the main surrounding earthwork.

The circular earthwork surrounding Stonehenge is therefore of later date than the mounds, and is therefore also of later date than the neighbouring Round Barrows.

(*c*) The Stonehenge stone structure was erected after the surrounding earthwork.

Stonehenge is therefore of later date than the neighbouring Round Barrows, and was probably constructed near the end of the Bronze Age or perhaps later.

By some archæologists this argument is considered absolutely conclusive. Rice Holmes, for example, remarks :

"The stones were certainly not standing when Round Barrows were first erected on Salisbury Plain ; for one is contained within the *vallum*, which, moreover, encroaches on another" ("Ancient Britain," p. 476).

It will be observed that the whole of this argument is based on the assumption that mound No. 94 is really a Bronze Age Barrow. The mere fact that in it was found a cremated interment is, however, inconclusive, as we know that the Round Barrow people had a cuckoo-like habit of depositing a cremation in an existing hole or position originally intended for some other purpose. Col. Hawley's recent discoveries in connection with the "Aubrey Holes" furnish examples of this practice.

On Colt Hoare's plan the positions of the two stones and of the two mounds are not correctly shown, and from that plan it would not appear that they had any particular relation to each other or to the general scheme of Stonehenge.

But if the carefully made measurements by Flinders Petrie be correctly plotted to a large scale some very significant facts concerning these Four Stations at once become apparent, *e.g.* :—

(*a*) The four positions (Nos. 91, 93, 92, 94) are absolutely symmetrical in reference to each other and to the general plan of Stonehenge.

(*b*) They are all four on the same circle, *i.e.* their centres are all at the same distance from the centre of the structure.

(*c*) If a line be drawn through the centres of the two stones (91 and 93), and another line be drawn through the centres of the two mounds (92 and 94), these lines will intersect at the centre of Stonehenge.

(*d*) The two lines drawn as specified under (*c*) are at an angle of 45° (or an eighth of a circle) with

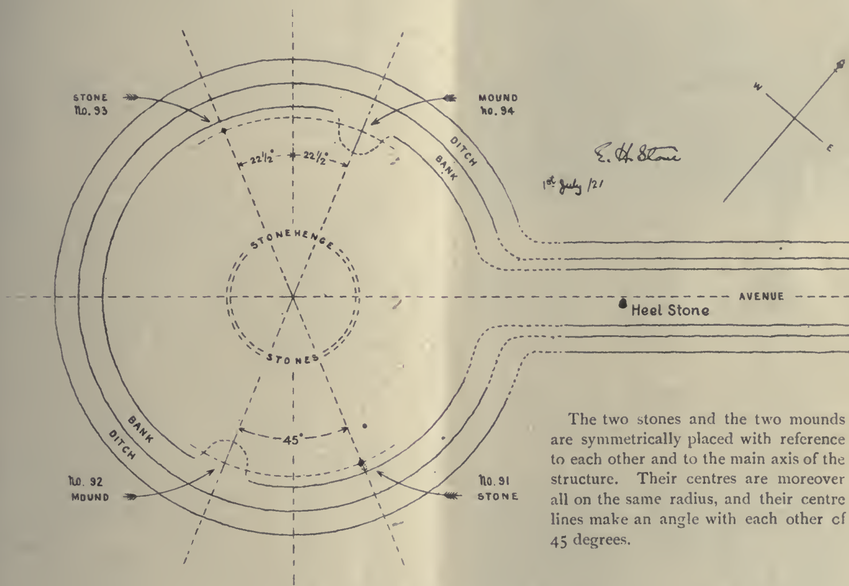

Fig. 1.—Plan of Stonehenge. Scale—120 feet to 1 inch.

each other. They moreover make equal angles of 22½° (or a sixteenth of a circle) with the cross centre line of Stonehenge.

This symmetry is very striking, and is so complete

Fig. 2.—Stone No. 91. To south-east.

that it cannot be accounted for as a mere coincidence. It obviously points to the conclusion that the Four Stations, Nos. 91 to 94, were all specially located in relation to one another as parts of one scheme to serve some definite purpose in the general design of Stonehenge.

Fig. 3.—Stone No. 93. To north-west.

On this Flinders Petrie remarks :—

"On examining the stones and mounds 91 to 94 on the earth bank it will be seen that they are exactly opposite, stone to stone, and mound to mound. This strongly shows that they are contemporaneous; as is also shown by the fact that the diameters joining their centres cross each other at . . . just half a right angle; and further the diameters are complementary to each other, being symmetrical about the axis of the structure" ("Stonehenge," p. 21).

We cannot doubt that at one time there was a stone in each of the positions now indicated by the two mounds; and that, whatever the purpose of the arrangement may have been, it had nothing to do with the neighbouring Round Barrows.

The two stones (Nos. 91 and 93), now in place, are shown in the accompanying photographs (Figs. 2 and 3). It will be observed that the ground is level around the base of each stone.

The two mounds (Nos. 92 and 94) are of very slight elevation, and are scarcely noticeable on the ground. Assuming that each of these two sites had at one time been occupied by a stone, we may suppose that the small amount of earth forming the present mound was thrown out of the excavation made when the stone was removed. When, later on, the cremated interment was buried, the incipient mound was perhaps trimmed up and added to.

It may be considered certain that the Four Stations were in no way connected with the "Aubrey Holes," and that they belong to a different period of Stonehenge history.

The Retreat, Devizes.

Improvement of Visibility of Distant Objects.

In connection with the subject of some recent letters in Nature on "A Method of Improving Visibility of Distant Objects" by Prof. C. V. Raman (October 20, 1921) and by Mr. A. G. Lowndes and Sir David Wilson-Barker (November 10, 1921), it may be of interest to mention that two years ago I published a complete essay on the same question in the French Bulletin Officiel de la Direction des Recherches Scientifiques et industrielles du Ministère de l'Instruction Publique, No. 4, February, 1920, pp. 229-48, under the title "Sur l'utilité de la lumière polarisée dans les observations faites en mer ou au bord de la mer, et sur une jumelle à polariseurs."

Every advantage of polarised light mentioned by your correspondents, such as improvement of optical contrasts, visibility of colours in distant objects, etc., was considered and discussed in detail in that paper. I must mention that I took the research in hand in 1916 for military purposes, in connection with the French Ministry of Invention and Research and with the French Admiralty. The results and my former reports were communicated to the English Board of Invention and Research (1917). A little later, Prof. W. F. Durand, of Leland Stanford University, then the Scientific Attaché to the American Embassy in Paris, having been kind enough to order the translation of my reports into English, that English version was given likewise to the official agent of the British Ministry of Munitions Optical Department, Mr. F. C. Dannatt, now representative of the British Scientific Apparatus Manufacturers, Ltd., in Paris. At the end of the war the French Navy had a small number of binoculars equipped with spar polarisers of the Glazebrook-Ahrens type cemented with a special oil, as described in my paper. The constructor, M. A. Jobin, member of the French Bureau des Longitudes, supplied a few of those binoculars, at the request of the British Government, through Mr. Dannatt.

I do not wish to take up the space available in Nature with a translation of my paper, but a short summary of a few of my conclusions may be of interest.

Contrary to Mr. Lowndes's opinion, I objected very

strongly to the tourmaline plates (except for some special purposes dealing with naval artillery) on account of the high colouring they give, either green or pink, which, unfortunately, results in an inaccurate rendering of the natural tints of objects and makes ineffective one of the most striking advantages of polarised light, the wonderful and delightful disclosure of true colours in far-distant objects.

Although the choice and careful making of the Bénard-Jobin spar prisms cemented by a special poppy-oil prepared by M. Duffieux (then my assistant) to equip the Jules Huet prism-binoculars of the French Navy gave unqualified satisfaction, I must confess—and I did so in the introduction of my paper—that I feel very much inclined to consider a very thin plate of *herapathite* (sulphatoperiodide of quinine) of a few square millimetres, having its crystallographic directions quite uniform in the whole area covering the ocular-ring, as the best of all polarising equipments. I cannot say it is the most practical one, because beautiful transparent and uniform herapathite plates are not easily obtained. However, I sincerely hope that my conclusion will please W. B. Herapath's fellow-countrymen, particularly as quinine salts are more easily obtained than Iceland spar.

Nevertheless, I mentioned at the end of p. 230 of my paper the old use of tourmaline spectacles to discover the fishes in deep water, and so on. *Nihil sub sole novum.* The optical constructor to whose talents I referred in my paper, without mentioning his name, as having, when he was a young man in the 'eighties, played a hoax on his fellow-anglers along the River Marne with tourmaline spectacles forty years ago, is now living in Grenoble. His name is M. Ivan Werlein, formerly well known and appreciated for his skilfulness by French physicists and crystallographers when he was working in Paris.

HENRI BÉNARD.

University of Bordeaux, February 8.

Statistical Studies of Evolution.

SINCE Dr. Willis and Mr. Udny Yule in their reply to my letter in NATURE (March 2) have asked me to explain the case of the New Zealand flora, I feel that I should attempt to do so.

The time taken for almost all animals and probably many plants to spread to the boundaries of a continuous area of habitable environment is short compared with geological time: witness the progress of *Elodea* in this country since its introduction only some sixty years ago. Surely, therefore, the majority of species at any particular time have already reached the boundaries of that area of habitable environment to which they are isolated (*e.g.* the Marsupials of the isolated Australian region).

Now the Indo-Malayan flora of New Zealand has arrived recently, geologically speaking, and has not yet reached a state of equilibrium; it is still spreading, unlike the majority of species. As Dr. Willis and Mr. Udny Yule showed clearly in their original article, the distribution of a fauna or flora that is still spreading will conform to the "Size and Area" curve. I believe that not only a spreading fauna or flora but also one which has reached the boundaries of its habitable environment will conform to the "Size and Area" curve.

The oldest endemic families of New Zealand must have reached this state of equilibrium and, on my theory, should conform to the "Size and Area" curve. Perhaps Dr. Willis could tell me if they do so in this or in a parallel case.

C. A. F. PANTIN.

Christ's College, Cambridge, March 13.

MR. PANTIN has not replied to our query as to why neither the northern nor the southern group of plants in New Zealand shows any increase of local species when it reaches the region where the other group shows its maximum of such forms. Why is one group represented by its most widely ranging endemics at the place where the other shows chiefly its endemics of least range?

If the Indo-Malayan invasion is so young in New Zealand, why do its members, though mostly trees, show a rather greater average range than those of the herbaceous southern invasion of plants of northern-hemisphere type? Though it is a long time since Britain was cut off from the Continent, why have 227 of its 1548 species not yet reached a distribution of more than 5 vice-counties out of 112, and why have only another 229 reached one exceeding 100?

All observation goes to show that dispersal of introductions is rarely rapid, unless, as in Ceylon or New Zealand, St. Helena or North America, man has completely altered the conditions, and destroyed or interfered with the societies that already existed. A few cases like *Elodea*, chiefly water plants, are known, and it is probable that the plant entered a society that was very incomplete. No other introduction has spread rapidly in England for centuries, though when the Romans came here, and cut down the forest, thus altering the conditions, many introductions were rapidly dispersed about the country.

To suppose that species have mostly reached their possible limit of dispersal is to return to a position like that taken up by the advocates of special creation, invoking incomprehensibility. Why should *Coleus barbatus* be found through tropical Asia and Africa, including the summit of Ritigala mountain in Ceylon, while *C. elongatus*, differing only in the form of the calyx and inflorescence, and a few minor points, is confined to that summit? Why should a species of the New Zealand flora that reaches the outlying islands range much further *in New Zealand* than a species that does not? Why should one that reaches the Chathams range much further than one that reaches the Aucklands or the Kermadecs? Nothing but Age and Area can even suggest an explanation of such facts.

No theory based upon natural selection will enable one to make predictions about distribution, whereas Age and Area has already been used successfully in this way nearly a hundred times, and has increased our knowledge of the subject. If we suppose that dispersal is already completed there is little left to investigate, and to explain the distribution of species about the world (as opposed to purely local dispersal) becomes a task that has been abandoned as hopeless by leading authorities upon distribution. The fact that Age and Area can be used for successful prediction shows that it is probably correct, and it offers an explanation incomparably simpler than does the natural selection theory, and explains with ease facts utterly incomprehensible to the latter, such as that the Auckland Is. contain 45 per cent. of Monocotyledons in their flora, the Chathams 31 per cent., and the Kermadecs only 21 per cent. How can natural selection explain the remarkable maps in *Ann. Bot.* 32, 1918, pp. 343 *seq.*, and the curves on pp. 357, 360? Mr. Pantin's theory seems to us to lend itself neither to explanation nor to prediction. We feel compelled again to emphasise that his supposition as to random combinations of environmental limitations does not appear to us to bear any relation to facts. Nor, if it did accord with facts, can we agree that his conclusions would follow.

J. C. WILLIS.
G. UDNY YULE.

Radiology and Physics.[1]

By DR. G. W. C. KAYE.

THE appreciation of the physicist by the medical worker in this country is of recent growth, but radiologists, while fully alive to the enormous part that radiology will play in medicine in the future, are only awakening to the fact that, if radiology is to advance as it should, they will have to correlate it continuously with physics. They may not find such correlation very easy. Not that physicists would look askance at the idea; the difficulty is that there are so few of them who are interested. The physicist has never been taught to look upon radiology as offering a possible career. Even had he been prepared to risk it, he would not have found educational facilities to put him on his way. There are probably not half a dozen physicists employed in radiology in this country. The Germans discovered, long before the war, that the secret of progress in radiology was to bring the medical man and physicist continually together and let them work side by side. They went further and introduced them both to the manufacturer—but that is another story! Is the British radiologist in a position to submit techniques, backed up with a wealth of physical and scientific data such as the German has recently given to the world? It is to be hoped so, but the British radiologist is sadly handicapped by not being able to look to the physicist for the discharge of duties which he has neither time nor, possibly, inclination to see to himself.

Radiology needs men who have a sound knowledge of the physics of radiology and are, furthermore, well grounded in electrical engineering, especially on the high-tension side of the subject. If we could ensure a steady supply of qualified physicists and electro-technicians who knew that in their future work they need not fear that they will not enjoy, both professionally and socially, the full status of their medical colleagues, we could look forward to a desirable all-round improvement in the science and art of British radiology.

Within the last decade we have learnt that X-rays are identical with light rays in almost every particular, the main difference being that the wave-lengths of the X-rays are much shorter. Until recently, a gap of about 4 octaves existed between the shortest known ultra-violet ray and the longest X-ray, but within the last few months it has been discovered that the continuity is complete and that the X-rays follow on and, indeed, overlap the ultra-violet end of the spectrum. The study of this missing group of octaves had invited attention for some time. The grating method proved unavailing for the purpose, the wave-lengths being too small for our artificially ruled gratings and too big for crystal gratings. Further, at either end of the gap the vacuum spectrometer had proved necessary owing to the extremely absorbable nature of the rays. The problem has finally been attacked with success in this country and America by Millikan, Richardson, Hughes, and Kurth who, using indirect photoelectric methods, have traced X-ray spectrum lines of various elements right across the gap and into the already explored ultra-violet. Fig. 1 shows the positions of some of these lines.

The following are the wave-lengths in Angström units, *i.e.* 10^{-8} cm. of the regions of the spectra we have been discussing:—

Visible light	7200 to 4000
Ultra-violet light	4000 to 200
X-rays	500 to 0·06
γ-rays	1·4 to 0·01

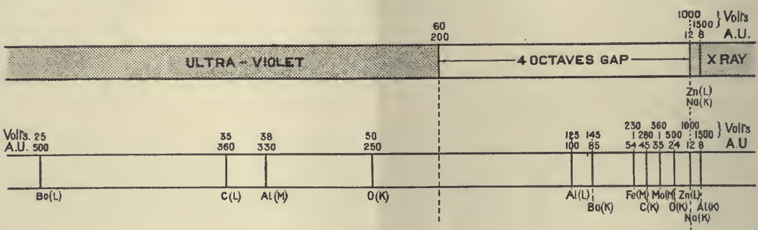

FIG. 1.

It thus appears that we can now claim a knowledge of the existence of over 13 octaves of X-rays or, including radium γ-rays, nearly 16 octaves. As yet the radiologist has only turned about 3 octaves of these to account.

As is now well known, the parallelism between light rays and X-rays is maintained by the presence of spectrum lines in the X-ray spectra. Just as the spectrum of a hot body normally consists of a continuous spectrum of white light, together with certain spectrum lines the wave-lengths of which are characteristic of the radiating material, so an element emitting X-rays not only gives out "white" radiation, but superposes its characteristic lines on the general spectrum. The characteristic X-ray spectra are found to be much less complicated than light spectra and are more readily sorted out into groups or series of associated lines. These several series, each of which includes a number of lines, are designated—J, K, L, M—and are broadly differentiated by a progressive increase in the average

[1] Abridged from the Mackenzie-Davidson Memorial Lecture delivered on February 17 at the Royal Society of Medicine.

wave-length of each group as we pass from one to another, series J having the shortest wave-length and requiring the highest voltage to excite it. It should be added that all the constituent lines of a group are excited simultaneously at a critical minimum voltage.

The work on X-ray spectra has thrown great light on the structure of the atom, and, in passing, it may be recalled that present-day theory regards all atoms, of whatever kind, as built up of two kinds of "bricks," and two only—(*a*) negatively charged electrons, and (*b*) hydrogen "nuclei," each more than 1800 times as heavy as an electron and carrying a charge equal to that on the electron, but positive in sign. Rutherford's nucleus theory of the atom, now universally accepted, regards an atom as built up of a minute positive nucleus (to which practically the whole mass of the atom is attributed) surrounded by a cluster of electrons grouped in rings. The total number of electrons in these rings is equal to the atomic number (N) of the atom in question. The nucleus of the atom is regarded as built up of hydrogen nuclei held together by electrons, the former being in excess to just such an extent that the nucleus as a whole contains N positive charges. This serves to counterbalance the N negative charges of the electron rings, the result being an electrically neutral atom. For example, platinum has an atomic number of 78. Its atomic weight determined chemically is 195. Thus, if platinum is a simple element, the platinum atom has a nucleus composed of 195 hydrogen nuclei and 117 electrons, the difference (78) serving to counterbalance the 78 electrons in the rings. The various elements differ only one from another in that they have different nuclear charges, the nucleus determining the mass and radioactive properties, while the number and grouping of the cluster of electrons in the rings control the chemical and spectroscopic properties. For example, the K radiation is supposed to arise from the displacement of an electron in the innermost ring, the L radiation from the next ring, and so on.

Within the last few years it has been established experimentally that there is a definite boundary to every spectrum of general X-rays on its short wave side. The position of this boundary (or quantum limit) is not affected by the nature of the element emitting the X-rays, but is dependent solely on the maximum voltage applied to the tube. The relationship is given by the well-known quantum equation of Planck. Substituting the accepted values of the constants, it follows that

$$\text{max. voltage} = \frac{12{,}400}{\text{shortest wave-length in A.U.}}$$

This very simple relation provides us with a scale of quality which, if not perfect, is more exact than any which the radiologist has been in the habit of using. Spectral curves of X-ray intensity are not symmetrical, the shortest waves are the dominating ones. The mean effective wave-length (or "centre of gravity") of a spectrum of rays approximates to the wave-length of the peak of the curve, *i.e.* the wave-length of maximum intensity. Now there is some evidence that this wave-length of the peak (λ_m) is proportional to the limiting or quantum wave-length (λ_o); in many cases λ_m proves to be approximately 4/3 times λ_o. But in practice it is much easier to measure λ_o than λ_m, and this fact gives an added importance to the measurement of the quantum limit and enables us to identify very fairly the quality of a mixed bundle of X-rays. No doubt something depends on the wave-form of the exciting potential, but the effect of this is probably less important as the voltage is raised. The precision of the method would be enhanced if steps were taken to standardise apparatus and technique, so that all work could be done by the use of, at most, three or four spectra the distinctive features of which, including energy distribution, could be determined and specified.

But how is the radiologist going to measure wave-lengths in his operating room? At present, the easiest plan appears to be by measuring the maximum voltage and using Planck's relation. The voltage can be obtained by use of a reliable type of electrostatic voltmeter, or, failing that, by measuring the alternative gap by means of some approved type of spark gap such as the sphere gap. Another and a better plan is to measure the quantum limit by means of a portable direct-reading spectrograph of the type designed in Germany by Seemann (Fig. 2). Incidentally, these direct-reading spectrographs act as very convenient

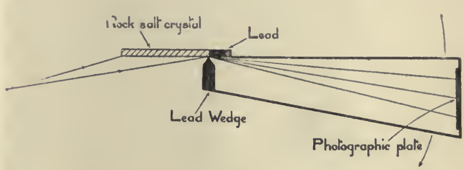

FIG. 2.

and accurate high-tension voltmeters, which afford a measure of the true maximum voltage effectively operating a tube.

There are two things that may happen to a beam of X-rays when passing through a material. Part of it may be absorbed, and is therefore wholly transformed into characteristic radiations of the material, the process always being accompanied by the liberation of electrons. The rest of the beam is scattered or dispersed which, in effect, is equivalent to stating that while the rays are unaltered in quality a considerable proportion of them have their direction altered. Scattering, which finds a close parallel in the dispersion of light by a fog, is more noticeable with light atoms than with heavy.

We explain these two effects—absorption and scattering—by supposing that absorption is caused by the flicking off by the X-ray of an electron in one of the ring systems in the atom. The outcome is the vibration of the ring systems in question with characteristic periods and the expulsion of an electron from the atom at high speed. If, on the other hand, it happens that the X-ray is incapable of definitely ejecting an encountered electron but merely jars it, so to speak, then the electron, having absorbed the energy of the X-ray, vibrates not with its own free period but with a forced period which is prescribed by the X-ray and it re-emits its new-found energy in all directions, though chiefly round and about the original direction. With a medium weight or heavy atom the proportion of scattered to absorbed radiation depends upon the wave-length and

may be small. With a light atom the amount of scattered radiation is almost always large.

The problems of scattering have come to the fore recently in radiology in connection with deep therapy. The human body is made up chiefly of carbon, hydrogen, and oxygen—all light atoms—and its ability to scatter X-rays in the adjacent air has long been familiar to radiologists, especially in screening work. But the extent of the scattering within the body itself is just as marked, and this is the case whether the rays are of medium or high penetration. It has been established by Dessauer and others, from measurements made on specified areas at various depths within the tissue, that from 60 to 80 per cent. of the effectiveness of highly penetrating rays is due to scattered rays which originally were not directed at the area in question.

The subject of protection has recently excited a great deal of attention by reason of a series of casualties to prominent radiologists. The various radiological societies and institutions in London co-operated in 1921 in the formation of a representative Committee, which was asked to go into the whole question and draw up recommendations for the guidance of all concerned. It was agreed that the question of the protection of the operator was the sole issue; the existing measures had proved to be adequate so far as the patient was concerned. The word "protection" was to be interpreted in a wide sense.

The Protection Committee was fortunate in securing Sir Humphry Rolleston as Chairman and, under his eminent leadership, has already drawn up two memoranda. They need not be referred to in detail here, but they have already been widely acted upon, and there is little doubt that presently the bogey of X-ray dangers will have been laid. In years to come this country will be entitled to congratulate itself on having given a lead to the world in this matter.

The Committee has laid down certain standards of protection against X- and γ-rays, which are expressed very simply in terms of the equivalent thickness of sheet lead. These thicknesses were based on available experimental data; for example, the X-rays from a tube excited by about 180,000 volts are cut down over 10,000 times by 3 mm. of lead, and over 1 million times by 10 mm. of lead. The choice of the actual protective material may, of course, be determined by insulating, electrostatic, or other considerations, but its thickness should be such as to provide protection equivalent to the amount of lead specified.

The Committee sought and secured the co-operation of the National Physical Laboratory, both in investigatory work and in the question of the inspection of existing X-ray departments in hospitals and other institutions. The N.P.L. has already inspected a number of X-ray departments throughout the country, and it may be said at once that, if the conditions which obtained there may be regarded as typical, the Protection Committee needs no justification in its labours. The Committee has adopted the common-sense principle that, wherever possible, the tube box or enclosure should form a complete shield in all directions, allowing only the minimum aperture for the work in hand. Few installations subscribe to this very reasonable demand. In some cases the scattered radiation in different parts of the X-ray rooms proved to be so excessive as to prohibit examination by electroscope, and observations had to be confined to noting the comparative ease with which the bones of the hand could be seen on a screen as it was carried round the room.

It is established that ventilation is of prime importance but, unfortunately, the radiological departments are generally situated in the basement. Ventilation difficulties are multiplied tenfold in consequence and, further, the rooms are largely shut off from the beneficent effects of sunshine. In the majority of cases the high-tension system consists of stretched over-head small gauge wires, connected by spring tapes, or spirally wound fine wires to the various apparatus. The resulting brush discharge produces ozone in abundance, and, as extractor fans are rarely fitted, the unfortunate operator gets the full benefit. The Protection Committee has recommended the use of smooth tubes or rods or heavily insulated wires with the object of abolishing the evils of brush discharge. It suggests the employment of commodious rooms with ample head room, especially in the case of deep therapy outfits where the exciting voltages are in the region of 200,000. Another danger is here indicated; more than one fatality has been occasioned by accidental discharge to an operator working in a small room with slack or looped high-tension wires.

Generous recognition should be paid to the X-ray manufacturers of this country for the way they are beginning to co-operate with the Committee. The British X-ray manufacturers, divided as they are, are mostly carrying on under great difficulties at the present time. Yet, despite their difficulties, almost all of them have taken steps to obtain from the National Physical Laboratory test figures for the various protective materials which they are incorporating into existing and new installations. Such measurements are rapidly and inexpensively carried out by the Laboratory, and no radiologist need deny himself the security which the N.P.L. certificate affords. The Laboratory experience amply confirms the necessity for such tests. For example, lead glass has been tested —of which only 5 mm. were required to give the protection of 1 mm. of lead. For other samples of glass as much as 10 mm. were required. The corresponding figures for lead rubber show variations between 1·7 mm. and 4 mm. as the equivalent of 1 mm. of lead. Thus, with either protective material a manufacturer can easily be 100 per cent. out in his reckoning if he employs uncertified material. He owes it to himself and his customers to take no such risks.

Two noteworthy steps, pregnant with promise for the future of radiology, were taken in the establishment of the Diploma in Radiology and the formation of the Society of Radiographers. Here again this country has taken the lead. And when some day we get an Institute of Radiology, with which Mackenzie-Davidson's name should be associated in some way, a further great step will have been taken to assist radiology in this country to take the proud position among the sciences to which its important and beneficent activities entitle it.

Forests in Relation to Stream-flow and Erosion.

One of the common marvels to the ordinary person is that so little is really known about such an everyday phenomenon as rainfall. It is a satisfaction to remember that, thanks to the British Rainfall Organization, more is known of the rainfall of Britain than of any other country, but our complacency may be a little disturbed when we reflect that for investigations as to what happens to the rain after it falls we have to turn to other lands. Water-engineers, indeed, have data from which much might be learned; but water engineers are secretive folk, and the records of investigations on the run-off of the Severn, Exe, and Medway remain the only records generally accessible. The results of these investigations, though extremely valuable, are not, however, very definite, as the areas are so large and the problems correspondingly complicated. More definite results are to be expected from the experiment being carried out by the United States Department of Agriculture in Colorado.[1] The areas dealt with are small and the problem more defined, though even in the small areas there studied conditions are by no means so simple as might be desired.

The intention of the experiment planned in 1909 was to make a complete study of the effects of forest cover on stream-flow and erosion. The main idea of the method employed is simple enough. It was, to select two small forest-covered valleys, contiguous, of the same size, similar and similarly situated, to find the rainfall and run-off from each, then cut down the forest from one of the areas and repeat observations. It appears almost a laboratory experiment. The first trouble was the trouble of the cook who desires to cook a hare, or perhaps it would be better to say, a brace of grouse, and it must be confessed at once that though two somewhat similar birds were caught they were not of the same kind, and as investigation proceeded unexpected anatomical differences presented themselves, extremely interesting in their own way, but not making for uniform cooking; it appears also that even if they had been both of a kind they were particularly difficult birds to cook. The valleys chosen lie about the 10,000 feet level in a region with precipitation about 20 inches a year, about half of which falls as snow and a goodly proportion of the rain in thunderstorms, both phenomena introducing difficulties.

The publication before us is a preliminary report giving an account of the first part of the experiment from 1911 to 1919, and discusses the data obtained while both valleys, A and B, were forest covered. Both valleys are small, B of 200 acres and A a little larger, varying in elevation from just over 9000 feet to just under 11,000 in the case of B, and somewhat over in the case of A. The geological structure is identical, namely, augite-quartz-latite, little porous to water, covered with a few feet of soil and decomposed rock, porous and sandy in texture, forming a permeable and well-drained top layer. The forest cover, conifers of various kinds, is almost identical. The valleys are not, however, of quite the same shape—A is long and narrow, B is much more like a bowl; the exposure is rather different, the centre line of A being south of east, while that of B is north of east. This is important in view of the fact that the winter snowfall runs off as it is melted by the summer sun, and indeed both the time and degree of response of the two streams to any factor influencing the *régime* are somewhat dissimilar. For example, after rainfall A rises more rapidly and reaches its maximum flow earlier than B, B may then be higher than A for a time, while at the end of the flood A may be higher than B. As a result, it has been necessary to construct tables and diagrams to show the relation of B/A for a great variety of conditions, and some 16 "rules" have been formulated for comparing the discharge of B when the discharge of A and the rainfall is known.

The readings for the run-off may probably be accepted. Very great care has been taken to construct suitable dams, gauges, and basins. The construction of the measuring apparatus is described in great detail, and the readings appear in general to have been exceedingly accurate and trustworthy. But it is a little difficult to place implicit confidence in either the precipitation statistics or the use that is made of them. Though details are, perhaps significantly, lacking, it is evident that the exposure of the gauges for rain and snow is not up to the standard required in this country, while their distribution also leaves something to be desired. Only five were set up in the two valleys; two are close together in the lower part of each basin and one at almost the highest point of A, while a sixth was just outside the lower portion of both basins.

The number would, of course, be abundant for ordinary rainfall work, but in a scientific experiment which is otherwise marked by accuracy, British experience would suggest that the number was inadequate, and we should imagine that over a vertical height of 2000 feet there would be considerable differences in rainfall, especially when a good proportion of the rain falls in thunderstorms. It is possible that conditions are different in Colorado, but we should have been more satisfied if evidence had been adduced to show that this was so. Nor is our confidence increased when we learn that in the second part of the experiment, when the forest is removed from B, only the gauges in the A valley are to be read. It is scarcely sufficient to say that "the use of the single record cannot be seriously objected to when it is considered that at the lower end of A there is the *choice of the better catch* of two gauges, and this value *is averaged* with the catch of the third gauge at the head of the valley." The italics are ours. It is only fair to say that much more care has been taken with another and equally important side of the problem, the melting of the snow. Observations of the depth of the snow at the time of thaw are taken at a considerable number of points.

It will be interesting to see in ten years' time the results of removing the forest. No doubt valuable results will be obtained which will be of use in dealing with the Forest Reservations of the Rockies, but even so, light will be thrown on only a small portion of the small problem. We shall know what is the effect of removing forest cover only under somewhat special conditions. There will be plenty room for further investigation.

Disintegration of Elements.

By Sir Ernest Rutherford, F.R.S.

I HAVE been asked to say a few words about a telegram in the *Times* of March 14 giving an account of a paper communicated to the American Chemical Society at Chicago by Dr. G. Wendt and Mr. C. E. Iron. It reported that, when a powerful condenser discharge at 100,000 volts was sent through a very fine tungsten wire, the filament exploded with a "deafening report," producing a flash estimated to correspond to a temperature of at least 50,000° F. The telegram states: "After the flash he (Dr. Wendt) found atoms of tungsten decomposed into simpler atoms and the result was the change of metallic tungsten into gaseous helium." The experiments were made to investigate whether any atomic disintegration can be effected by such high temperature discharges, and apparently the authors believe that they have obtained positive results.

We must await a much fuller account of the experiments before any definite judgment can be formed; but it may be of interest to direct attention to one or two general points. During the last ten years many experiments have been recorded in which small traces of helium have been liberated in vacuum tubes in intense electric discharges, and it has been generally assumed that this helium has been in some way occluded in the bombarded material. On modern views, we should anticipate that the disintegration of a heavy atom into lighter atoms, *e.g.* into atoms of helium, would be accompanied by a large evolution of energy. Indeed, it is to be anticipated that the additional heating effect due to this liberated energy would be a much more definite and more delicate test of disintegration of heavy atoms into helium than the spectroscope.

Our common experience of the large effect of temperature in ordinary chemical reactions tends to make us take a rather exaggerated view of the probable effects of high temperatures on the stability of atoms. While it seems quite probable that momentary temperatures of 50,000° F. can be obtained under suitable conditions in condenser discharges, it should be borne in mind that the average energy of the electrons in temperature equilibrium with the atoms at this temperature corresponds to a fall of potential of only 6 volts. In many physical experiments we habitually employ streams of electrons of much higher energy and yet no certain trace of disintegration has been noted. In particular, in Coolidge tubes an intense stream of electrons of energy about 100,000 volts is constantly employed to bombard a tungsten target for long intervals, but no evolution of helium has so far been observed.

Obituary.

Prof. A. D. Waller, F.R.S.

BY the death of Prof. Augustus Désiré Waller, on March 11, in his sixty-sixth year, the scientific world has lost an unique personality—a physiologist of international eminence and of exceptional calibre.

Waller studied in the Universities of Aberdeen and of Edinburgh, graduated in the former, and commenced his experimental work in Ludwig's laboratory in the year 1878. From here he proceeded to University College, London, whence he was appointed to the lectureship in physiology in the London School of Medicine for Women. He subsequently held the corresponding post in the Medical School of St. Mary's Hospital. In 1902 Waller became Director of the Physiological Laboratory of the University of London, of which, aided by the generosity of his brothers-in-law, and enabled by the wisdom and liberality of the Senate, he had been largely instrumental in securing the foundation. This post he held, amid difficulties, with conspicuous success, until his death.

Whilst at St. Mary's, Waller had felt the need of and had found the time and energy to establish and equip a library and laboratory, in his home, and it was there that most of his earlier researches were carried out. From there also he supplemented the resources of the University by the unstinted loan both of books and of valuable apparatus. He was closely associated with the Institut Marey from its inception, latterly as vice-president, and took an active part in the direction of its affairs.

Nearly 200 publications, covering a very wide field, stand to Waller's credit. Early papers on the circulatory system led to a study of the electromotive phenomena of the heart beat and to the discovery that an electrocardiogram could be recorded on the human subject. His earliest records with the capillary electrometer, though accurate, were not what he expected them to be. Influenced by this, and misled by an insensitive instrument, he subsequently published and afterwards withdrew an inaccurate picture of the electrical events in the cardiac cycle. In consequence of this mischance the credit of Waller's discovery has been wrongly attributed to others. Some years later, with the aid of a more perfect instrument—Einthoven's string galvanometer—he returned to this work, which had been meanwhile developed and extended by Prof. Einthoven in Leiden. Thanks to Waller, the string galvanometer became now, for the first time, available for clinical diagnosis in London. Its employment spread from his laboratory in all directions, notably to University College Hospital and to the National Hospital for Diseases of the Heart, in the latter of which he was appointed consulting physician.

This, though perhaps the most notable piece of Waller's electro-physiological work, was a small fraction of its total. He was the pioneer of galvanography in physiology and was the first to record, photographically, the negative variation and the electrotonic currents of nerve, both of which he studied exhaustively. Of especial interest, in this connexion, are (1) his discovery that protracted excitation of a nerve produced the same effect on subsequent negative

variations as did the administration of carbon dioxide, and (2) his inference that this similarity implied liberation of carbon dioxide by the nerve. He investigated also, in full detail, the "Nach-strom" of earlier German writers. He called this the "blaze-current," found it to be one of the earliest and last signs of life, and applied it successfully as a test of vitality in seeds.

Waller devoted much time and energy to anæsthetics, studying their effects on surviving tissues and organs as well as on the intact organism. He also devised methods for estimating the concentration of anæsthetic vapours in air and apparatus for controlling their dosage.

During the last few years Waller concerned himself chiefly with the psycho-galvanic reflex and with the physiological cost of muscular work. In the first case he elaborated and improved pre-existing technique and made valuable observations—*e.g.* on the distribution of the emotive response. The second problem he tackled with all his energy and enthusiasm. Realising the importance of testing the workman, with the least possible disturbance, in the course of his normal job, he pushed simplification of apparatus and technique to the utmost. By this he made it possible to estimate expired carbon dioxide anywhere, at short notice, and from large numbers of subjects. He did not think that his results yielded information so precise as that obtainable from more detailed analyses and more complicated and cumbrous apparatus. He urged, however, that with his simplified technique he was able to accumulate data which could not be obtained, during a normal job, by the more complicated procedures, and claimed that these data furnished a good first approximation to the physiological cost of various kinds of labour.

Lack of space prevents detailed analysis of Waller's remaining work. He made valuable contributions on the laws of excitation and of sensation, on the sense of effort, on the relation between stimulation and response, on retinal and cutaneous currents, on the kneejerk and other neuromuscular phenomena in man. He worked also with plants—on photo-electric responses, and on growth, as well as on the testing of seeds already mentioned.

In addition to his papers Waller wrote an exceptionally original "Introduction to Human Physiology." This was followed by volumes of lectures—on animal electricity—the signs of life—physiology the servant of medicine—the electrical action of the human heart, and by a very suggestive essay on the psychology of logic.

Of his public services in the foundation and direction of his laboratory it is difficult to speak too warmly. On the opening of the laboratory Waller instituted short courses of research lectures, without fee, the first of which was delivered by himself. This was followed by similar courses by physiologists from other laboratories, not merely of London but also of Oxford, Cambridge, the Colonies, Europe, and the United States. The value of such lectures proved to be so great that they were promptly adopted by most of the colleges and schools of the University, not only in physiology but also in other branches of experimental science.

Not merely problems of academic science but problems of applied physiology, in the broadest conception of the term, were undertaken by the many who utilised the laboratory for research. Some such problems have already been mentioned, and to these may be added, *e.g.*, the chemistry of metabolic processes and products; the distribution of anæsthetics in the blood; snake poison; memory, mental fatigue; surgical shock, tetanus; the testing, assaying, and standardisation of drugs; the poison gases of the war; dietetics—studied by men of such varied interests as Sir Leonard Rogers, Sir Sidney Russell Wells, Sir William Willcox, Sir Frederic Hewitt, Sir Thomas Lewis, Prof. Gamgee, Prof. Buckmaster, Prof. M. C. Potter, Prof. F. W. Hobday, Dr. F. W. Pavy, Dr. George Oliver, Dr. F. S. Locke, in addition to the laboratory staff and a whole host of younger workers. The laboratory itself and its earlier work have been dealt with more fully in a special article in NATURE of March 9, 1905, p. 441.

Waller was elected a fellow of the Royal Society in 1892. The Academies of Science of Paris and of Bologna also recognised his work, the former awarding him a Prix Montyon, the latter the Premio Aldini sul Galvanismo.

We spoke of Waller as an unique personality. He was extraordinarily energetic and able, combining boyish impetuosity and rashness with great acumen and exceptional intellectual power. He made unusually warm friends, unusually bitter enemies, and was only appreciated adequately by the greater among his scientific contemporaries and by the more intimate of his personal friends.

W. L. S.

NEWS has been received of the death, on February 3, of Professor Vladimir Ivanovitch Palladin, who for many years had been Professor of Plant Anatomy and Physiology in the University of Petrograd. Professor Palladin's contributions to botanical science consist of numerous publications, from 1886 onwards, recording his researches in vegetable physiology. These are chiefly of a biochemical nature, and many of them are concerned with the respiration of plants, some of Palladin's investigations on this subject having led him to formulate his theory regarding "respiration-pigments" and oxidases. The decomposition of proteids in plants, the formation of chlorophyll, and alcoholic fermentation are among the other subjects which he studied. An English edition of Palladin's text-book on plant physiology was published in Philadelphia in 1918, having been previously translated into both German and French.

WE see with much regret the announcement of the death on March 24, at fifty-eight years of age, of Prof. W. B. Bottomley, Professor of Botany at King's College, London, from 1893 to 1921.

WE much regret to record the death on March 21, in his eighty-second year, of Dr. J. T. Merz, author of *The History of European Thought in the Nineteenth Century*, and other notable works.

THE *Chemiker Zeitung* announces the death, at the age of 54, of Prof. Emil Heyn, director of the Kaiser Wilhelm Institut für Metallforschung, Berlin-Dahlem. Prof. Heyn was well known to metallurgists for his researches on alloys.

Current Topics and Events.

The thirteenth Kelvin Lecture of the Institution of Electrical Engineers by Sir Ernest Rutherford on "Electricity and Matter" will be delivered at 6 o'clock on May 18, and not on May 11 as previously announced.

Dr. Ernest Barker, Principal of King's College, London; Dr. A. E. Cowley, Oxford, Bodley's Librarian; and Dr. G. C. Simpson, Director of the Meteorological Office, have been elected members of the Athenæum Club under the provisions of the rule of the club which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public service."

The library of the Rothamsted Experimental Station, Harpenden, one of the best agricultural libraries in the Empire, has recently been enriched by a rare volume (believed to be the first printed book on agriculture in France) given by Lady Ludlow, who has on several previous occasions made important gifts to this institution. The volume is entitled "Le livre des prouffitz champestres et ruraulx," and was printed by Pierre de Sainte Lucie at Lyons in 1539. It is of special interest in view of the influence exerted by the French agricultural authors of a somewhat later period on the Elizabethan agricultural writers in this country, whose influence in turn lasted almost to Victorian times.

Captain Amundsen's plans for his new Arctic Expedition for drifting across the polar basin in the *Maud* are now complete. The *Times* announces that Capt. Amundsen has left Norway to rejoin his ship at Seattle, where it has been refitted for the voyage. Sailing on June 1, Capt. Amundsen expects to enter the ice near Wrangell Island at the end of July, and hopes to reach Greenland or Spitsbergen in four or perhaps five years' time. The crew will consist of ten all told, including one Eskimo. An aeroplane for reconnaissance work is to be carried. The ship's wireless equipment has been much strengthened and now has a radius of 2000 miles. It is expected that the high-power station at Stavanger will be able to reach the *Maud* throughout its voyage. Capt. Amundsen proposes to send daily weather messages via Washington.

The summer meeting of the Institution of Electrical Engineers at the Scottish centre will be held at Glasgow on May 30-June 2 next. A paper will be read on May 31 at the University of Glasgow by Prof. Magnus Maclean on the hydro-electric resources of the Scottish Highlands, and the remainder of the meeting will be spent in visiting works and electrical installations. Arrangements have been made for tours of inspection of a number of power stations and works in the neighbourhood of Glasgow, and a two-day excursion will be made to Oban and Kinlochleven, where the British Aluminium Company's hydro-electric installation will be visited.

A summary of temperature, rainfall, and sunshine for the several districts of the United Kingdom for the winter season comprised by the 13 weeks from November 27, 1921, to February 25, 1922, was given in the *Weekly Weather Report* ending February 25. The mean temperature for the period was in excess of the average in all districts, the greatest excesses being 2°·8 F. in the north and south of Ireland, and 2°·2 F. in the English Channel district. In the south-east of England the excess was 1°·4 F. The least excess in any district was 0°·7 F. in the east of Scotland and the north-east of England. The rainfall was in excess of the average for the winter in all districts except in the south-east and south-west of England and in the English Channel. The deficiency in the south-east of England was only 0·16 in., but in the other two districts it amounted to 1·4 in. In the west of Scotland the excess was 3·70 in., the rainfall measurement being 17·98 in. The duration of bright sunshine was generally in fair agreement with the normal.

The exhibition of travel films, now being held at the Philharmonic Hall, London, under the direction of Brig.-General Sir Percy Sykes, is due to the enterprise and enthusiasm of a number of soldiers and explorers. The idea which inspired the undertaking is an excellent one and it is being admirably carried out. Each series of pictures is being produced by men who possess special qualifications for the task, and the journey is to be described either by the leader of the expedition or by a traveller well acquainted with the country. The exhibition, therefore, is of great educational value, and in many respects it differs entirely from the ordinary picture show. In the case of Burma, the pictures (by the Solar Films Co.) have been carefully selected in order to give a vivid conception of the various aspects of the people and the country. The wonderful Schwe Dagon Pagoda near Rangoon is first shown, and then scenes on the river Irrawaddy and in the hill country round Bhamo, followed by a thrilling railway journey through the tropical forest and across the Gokteik Bridge. On the way back to Rangoon the Royal Palace and shrines at Mandalay are shown. In the course of the journey the natives are seen weaving silk, climbing trees to get orchids, rowing boats with their legs instead of their arms, and directing elephants engaged in moving teak logs. The pictures, assisted by Maj.-Gen. Dunsterville's interesting explanations, leave a clear impression on the mind alike of the country, the people, and the conditions under which the Burmese live. This exhibition is to be followed by travel films of Morocco, Andalusia, Timbuctu, the Land of the Incas, and Persia.

Sir Robert Robertson gave an instructive survey of the work and scope of a scientific society in his presidential address to the West Kent Scientific Society on February 27. During the last four years forty-six papers have been read before the society, and of these nearly one-third have dealt with subjects

belonging to physics and applied physics. Next in order of numbers come zoology and chemistry—each making about one-sixth of the total—and then follow astronomy, physiology, geology, sociology, and mathematics. About 60 per cent. of the papers were by members of the society and the remainder were by visitors. In most cases the papers were descriptive accounts of results of recent work and progress in particular fields, presented so as to be intelligible to scientific workers generally rather than to specialists. The West Kent Scientific Society, like most local scientific societies, thus fulfils on a small scale, and for its own area, the functions of the British Association with which it is affiliated. Few local societies can expect to receive many communications containing new results of original investigations; first, because their proceedings, if published, are rarely easily accessible or widely distributed, and next because recognised specialist societies are usually ready to accept and publish such papers. A local scientific society ought, however, to be recognised as the natural body to be consulted upon all local matters in which scientific knowledge or guidance is required, just as the Chamber of Commerce is for commercial questions; and it is in this direction that such societies may exert most valuable social influence. Sir Robert Robertson's address ought to do something towards promoting federation and development with this end in view.

Prof. A P. Laurie's discourse delivered at the Royal Institution on February 17, on Pigments and Mediums of the Old Masters, began with the Egyptian Blue used in Egypt from the IVth Dynasty, which he had identified on the wall paintings in Crete in the Palace of Knossos. This became ultimately the blue used for wall paintings throughout the Roman Empire. Prof. Laurie has shown that it is formed within a limited range of temperature at about 850° C. when sand, copper carbonate, soda, and lime are heated together for a considerable time. The green found on Egyptian paintings is formed when the magma is raised to a higher temperature. Prof. Laurie has traced the use of this blue until about the end of the 2nd century, but it is not found on the earliest Byzantine illuminated manuscripts of the 7th century which are in the possession of the British Museum, being replaced by a badly washed ultramarine from lapis lazuli. Prof. Laurie also referred briefly to the pigments used in classical times as described by Pliny, and found by Sir Humphry Davy and other researchers on Pompeian frescoes, and traced the pigments used from 700 up to 1700 as determined, partly by literary evidence and principally by the actual examination of illuminated manuscripts, pictures, and legal rolls in the possession of the Record Office and Venetian Ducali. The history of pigments brings out interesting points, such as the close agreement between the pigments used on the Lindisfarne Gospels and Scoto-Irish manuscripts with those used in Byzantium, the gradual improvement in the preparation of ultramarine and the use of a green which was apparently verdigris dissolved in Venice turpentine. This is apparently the green found in the Van Eycks and other pictures of the 15th and early 16th centuries. Azurite was used almost universally as a blue from about 1480 to 1640, and was replaced by smalt and by an artificial copper carbonate known as blue bice. Prof. Laurie also described how tiny samples could be taken from a picture without injury, and showed the scheme of analysis for the identification of blue pigments, explaining the value of such inquiries for fixing the dates of pictures and detecting forgeries.

At the monthly meeting of the Zoological Society of London, held on March 15, the Secretary directed special attention to the acquisition by the Society of two Indian elephants presented by H.H. The Gaekwar of Baroda, a lioness, bred in India, presented by H.H. The Maharajah of Magurbhanj, and an Allamand's Grison from Pernambuco presented by Lieut.-Commander Rutherford Collins. Thirty-two new fellows were elected to the Society and thirty-five candidates proposed for fellowship. During February 126 additions to the Society's menagerie were received, 39 by presentation, 81 deposited, 5 by purchase, and one born in the gardens.

The National Union of Scientific Workers has received a number of scientific publications from the People's Commissary for Education in Russia among which are the following: "History of the World," by K. N. Malinin; "Man: his Origin, his Structure, his Future," by C. A. Chugunof; "The Foundations of Life," by P. M. Schmidt; "Life," by Sir Edward A. Sharpey Schafer, a translation of his presidential address to the British Association for the Advancement of Science delivered at the Dundee meeting in 1912; "Outline of the History of Geological Knowledge," by A. P. Pavlov; and "Spectrum Analysis and the Structure of the Atom," by D. C. Rojdestvinski. The National Union of Scientific Workers is willing to endeavour to arrange with the Russian Commissary for Education for the exchange of scientific publications between men of science in Great Britain and Russia.

In issuing their new quarto catalogue of scientific apparatus Messrs. Pye and Co. of Cambridge invite special attention to the reduced prices, which they claim are now in many cases down to pre-war level. A number of new pieces of apparatus are described, including an X-ray spectrometer, a fluxmeter, a reflecting moving coil galvanometer at 3*l.* 10*s.*, a Rayleigh stroboscope and a centrifugal force machine. A large proportion of the apparatus intended for the use of students has been designed by Dr. Searle. The catalogue consists of 150 pages, well printed and illustrated, and is bound in stiff cloth covers. The name of the firm on the front page of the cover is very readable, but there is no name on the back, and when the catalogue is placed on the shelf amongst others there is nothing except the colour of the cover to indicate whose it is. It is curious that our instrument makers should desire to render their catalogues inconspicuous in this way, but there can be no doubt about the fact, as this is the fourth case which has come to our notice in the past few months.

Our Astronomical Column.

Ratios of Planetary Distances.—Mr. F. A. Black, 57 Academy Street, Inverness, sends us a communication in which he points out a fairly close approximation which connects the ratios of the planetary distances. Using the names of the planets to denote their respective mean distances from the sun, then

$$\frac{\text{Mercury}+\text{Earth}}{\text{Venus}+\text{Mars}}=\frac{\text{Jupiter}+\text{Uranus}}{\text{Saturn}+\text{Neptune}}.$$

The logarithms of the ratios are 9·79050 and 9·78935 respectively. The approximation is sufficiently close to be interesting, though it is unlikely that it has any physical basis. It will, of course, be observed that corresponding members of the inner and outer planetary groups occupy corresponding places on the two sides of the equation.

Reid's Comet, 1922 (*a*).—Mr. H. E. Wood has computed revised elements of this comet, from Johannesburg observations on January 23 and 30, and February 5.

$$\begin{aligned} T &= 1921 \text{ October } 26{\cdot}40738 \text{ G.M.T.} \\ \left.\begin{aligned}\omega &= 183^\circ\ 31'\ \ 9{\cdot}4'' \\ \Omega &= 275^\circ\ \ 6'\ 26{\cdot}8'' \\ i &= \ 32^\circ\ 56'\ \ 6{\cdot}1''\end{aligned}\right\} &\ 1922{\cdot}0 \\ \log q &= 0{\cdot}2183570 \end{aligned}$$

The comet was photographed by Prof. Barnard on February 3, when it was of magnitude 10; it is now fading. The comet passed perihelion 86 days before discovery, and was fairly well placed for northern observers last autumn, reaching its maximum brightness (about $9\frac{1}{2}$ mag.) on December 1. The fact that it then escaped observation suggests that many comets may pass their perihelion undetected and also that possibly the search for them is not being carried on quite so assiduously as before the war. As the comet is out of reach of European observers and growing fainter, it is useless to give an ephemeris.

Wireless Time-Signals.—There are four papers on this subject in the January issue of the Mon. Not. R.A.S., from the Greenwich, Pulkovo, Uccle, and Edinburgh observatories. Prof. Sampson, in the last-named paper, brings out the facility which these signals afford for determining the errors of the individual time-determinations, for the mean of them all may be assumed to be a satisfactory datum-line. He gives curves of the errors, which demonstrate the curious fact that each observatory is liable to be in error by as much as 0·2 sec., and that the error frequently persists for some weeks in the same direction. The cause is obscure; lateral refraction, due to dissymmetry in the distribution of atmospheric pressure is examined but is insufficient to explain the whole anomaly. Prof. Sampson infers that the observations throw grave doubts on the exactitude of accepted longitude results, which generally rest on special observations made during limited periods. It seems likely that better results may be obtained by using the whole of the clock comparisons made by wireless over periods of several years. Under the old method of observing, personal equation necessitated interchange of observers, but with the travelling-wire method the difference of observers is reduced to vanishing point. There are two precautions to be observed: first, the time-signals, which are necessarily made with a predicted value of clock-rate, must be corrected by later observations at the sending observatory; secondly, the same system of R.A. of clock stars and mean sun must be employed at both stations; it may be pointed out that the *Connaissance des temps* value of the R.A. of mean sun (used at Paris) differs by 0·06 sec. from the value in the Nautical Almanac; the former uses Le Verrier's solar tables, the latter Newcomb's.

Stars of the β Canis Majoris Type.—The Journal of Royal Astronomical Society of Canada for February contains a study of these stars by F. Henroteau. They were at first supposed to be simply spectroscopic binaries, with periods of 3 to 6 hours; but the author expresses doubt as to whether this is the true explanation of the changes of wavelength, as the amplitudes, shape, and periods of the velocity curves all show variations, as do also the widths and intensities of the spectral lines. A list is given of 24 stars suspected to be of this type: one of them is 12 Lacertæ, which Prof. Guthnick has investigated with the photo-electric photometer at Babelsberg, finding a small light-variation in the same period as the change of radial velocity. The suggestion is made that they may be binaries in course of formation, rotating Jacobian ellipsoids, or binaries disturbed by a third companion. The stars are nearly all of type B, which is the type where Dr. Jeans found that fission is most likely to take place.

Spectroscopic Parallaxes with Objective Prism Spectrograms.—It has been thought that slit spectrograms on a large scale were necessary for the determination of spectroscopic parallaxes, but Dr. Harlow Shapley and Mr. Bertil Lindblad show in Harvard College Observ. Circ. No. 228 that good results can be obtained using the large stock of objective prism spectrograms available at Harvard. The pair of lines most used are 4215 (ionised strontium) and 4326 (iron); use was also made of the cyanogen bands and the lines of hydrogen, calcium, and manganese. The research is at present limited to naked-eye stars of types Ko to K2. A list of fifty parallaxes is given; the largest being λ Sagittarii 0·113″, and δ Leporis 0·091″ (this large value accords with its proper motion of 0·696″). The probable error of a deduced absolute magnitude is of the order of 0·3 mag., which is satisfactorily small.

The Sun's Rotation from Spectroheliograms. The spectroheliograms used in this investigation[1] were taken at the Yerkes Observatory between 1903 and 1909 by Prof. Philip Fox, Director of the Dearborn Observatory. The conversion into heliographic longitude and latitude was effected graphically, the image being projected by a lantern on to a globe marked with circles and tilted into the requisite position. The following formulæ were deduced for ξ, the mean daily motion:—

Northern hemisphere . $\xi = 11^\circ{\cdot}107 + 3^\circ{\cdot}449 \cos^2\phi$.
Southern " . $\xi = 12^\circ{\cdot}143 + 2^\circ{\cdot}408 \cos^2\phi$.

The differential motion of flocculi round spots is investigated, and is found to indicate an *anticyclonic* whirl, *i.e.* opposite to the rotation of the sun on its axis, in the case of single spots, while it is *cyclonic* round the leading spots of bipolar groups.

A diagram is given comparing Fox's results with those of other observers. It shows that the angular speeds of the following classes of objects form an ascending series, the increase from first to last being about 1° per day: Reversing layer, Sun-spots, Faculæ, and Flocculi (present work), λ4227 (Adams), Hα (Adams).

Research Items.

AN AMERICAN PITT-RIVERS MUSEUM.—The famous ethnological collection made by General Pitt-Rivers first became known to students when it was exhibited at the Bethnal Green Museum in 1874–75. In 1883 it was presented to the University of Oxford, and since then, under the direction of Mr. Henry Balfour, its value has greatly increased. The distinguishing feature of this museum is that the exhibits are arranged, not in geographical or racial order, but in series illustrating the evolution of the chief human inventions. A collection of the same kind was made by the authorities of the United States National Museum for the Trans-Mississippi Exhibition held at Omaha in 1898, and since then it has been developed by distinguished anthropologists like Mason, Holmes, and Walter Hough, the author of an interesting pamphlet discussing it, entitled "Synoptic Series of Objects in the United States National Museum illustrating the History of Inventions." This pamphlet describes, with a good series of illustrations, the chief inventions in the order of their development—fire-making, torches and candles, lamps, cooking utensils, knives and forks, and so on. The vast resources of the American collections have produced a fine series of examples. The present pamphlet, adapted to our collections, might well serve as the basis for a popular manual of ethnology.

STONE IMPLEMENTS IN THE PERTH MUSEUM.—It is a matter of great importance that the collections in our provincial museums should be made more readily accessible to students. They often contain exhibits of considerable value, either the result of excavations in some local area with its store of antiquities, or of the benefactions of local collectors or of travellers who have brought material from abroad and are proud to share it with their neighbours. The student, if catalogues are available, will often find stored away in some local collection just the link which he needs in some line of research. Perth in its museum happily possesses exhibits of both these types—some implements locally discovered, and those brought from foreign countries. In the Transactions of the Perthshire Society of Natural Science (vol. vii, part 3) Mr. J. Asher publishes an excellent catalogue of the collection, with full descriptive notes and photographs of the more interesting specimens. He has also given references to works of authority, Proceedings of learned societies, and the like, in which objects of a similar type are described or discussed, and it is satisfactory to learn that copies of all the publications to which reference is made are to be found in the Society's library. The Society has set a good example, which should be followed in the case of all provincial museums.

INDIAN FISHING TRIBES IN VANCOUVER'S ISLAND.—The thirty-fifth annual report of the Bureau of American Ethnology for the year 1913–14 is somewhat belated owing to the war, but it contains matter of much importance. It is devoted to a monograph by Dr. Franz Boas on the Kwakiutl, a name applied to a group of Indians on the Pacific coast in the vicinity of Fort Rupert, Vancouver's Island. Dr. Boas has edited the material collected by Mr. G. Hunt, a mixed-blood Kwakiutl. This group of Indians now numbers about 2000 souls, but it is gradually decreasing. They speak languages of the Wakashan linguistic stock, closely allied to the Nootka. Many tribes on this part of the coast, gaining their livelihood by fishing, are distinct both in physical characteristics and language, but their culture is of an uniform type, and their industries, arts, beliefs, and customs are markedly different from those of all other Indian peoples. Closer study, however, discloses many elements peculiar to single tribes, which show that this culture is the natural result of a gradual and convergent development from several distinct sources or centres, every one of these tribes having added something peculiar to itself to the sum of this development. This monograph will hold a high place among the publications of the Bureau, and it is full of interest to the anthropologist, sociologist, and student of folk-lore. In particular, the account of food and cooking, due to Mrs. Hunt, an accomplished housewife, is admirable. The detail of fishing customs is more elaborate, and there are important sections on birth, in particular on the subject of twins, and the customs of distributing the trophies of the chase. For the philologist the text is supplied both in English and in the local dialect.

NEW SURVEYS ON THE ARCTIC COAST OF ASIA.—While exploring the North-east Passage in 1918–19, Capt. R. Amundsen wintered his vessel, the *Maud*, in lat. 77° 32′ 36″ N., long. 105° 40′ E., in the vicinity of Cape Chelyuskin, the most northerly point of the mainland of Asia. During the five months spent at Maud Haven a considerable amount of useful survey work was carried out in Taimir peninsula. Mr. H. U. Sverdrup, a member of the expedition, gives an account of this work, accompanied by a chart in *Naturen* (January-February 1922), the publication of the Bergen Museum. The previous map of Taimir Land was very incomplete, although considerable detail on the coast line was added by Vilkitski in 1913. The map now shows a long fjord on the east, where only a bay had been previously known. Toll Bay, on the south-west, also ends in two long narrow fjords. Exploration of the interior reveals a plateau-like structure where the range of the Birranga Mountains were formerly placed. Around the plateau lies a raised beach some five to twenty miles in width. Observations place Cape Chelyuskin in lat. 77° 43′ 26″ N., long. 104° 17′ E. No new surveys appear to have been made in Nikolas Land and Alexis Island, although the Norwegians visited the latter. The paper also contains a summary of the meteorological observations taken at Maud Haven.

RAINS OF FISHES.—For just on four hundred years circumstantial stories of fish falling with rain have appeared in various parts of the world. Naturally, such strange occurrences have given rise to much speculation and many even stranger theories by way of explanation. The whole subject is admirably reviewed by Dr. E. W. Gudger in the November-December issue of *Natural History*—the Official Organ of the American Museum of Natural History, which has just reached us. Dr. Gudger accepts such occurrences, and rightly, as well authenticated; he accounts for them as due to the agency of high winds, whirlwinds, and water-spouts, which could easily draw up either from the sea or rivers, shoals of small fishes swimming at the surface in the track of these uplifting agencies. As their force is spent they distribute their victims along their path.

BREEDING HABITS OF THE MERLIN.—A series of very valuable and interesting notes on the breeding habits of the merlin was commenced some time ago in *British Birds*. In the March issue, Mr. W. Rowan, the author, describes the rearing of the young.

The task of feeding them falls entirely upon the female, though the food is always brought to her by the male, who also feeds his mate. He brings her but two meals daily, one just after sunrise, the other just before sunset. But these are supplemented by small portions taken from the supply brought for the young. Titlarks formed 90 per cent. of the prey, which included also skylarks, thrushes, ring-ousel, and snipe. Invariably the victims were beheaded and deplumed at a distance from the nest. At times, however, some were brought partially plucked, when the female would give each youngster in turn a mouthful of feathers only, the mother herself partaking, apparently for digestive purposes. Mr. Rowan was never able to satisfy himself as to the means by which the transference of the prey from the male to his mate was effected. As he hove in sight she would fly out to meet him, then at incredible speed pass beneath him and seize the prey. But whether it was dropped, or snatched from his talons, he could never discover.

SHELL-STRUCTURE IN FORAMINIFERA.—Prof. W. J. Sollas, from an examination of the widely known Carboniferous foraminifer, *Saccammina Carteri*, has been led to make a detailed study of the shells of calcareous foraminifera in general (*Quart. Journ. Geol. Soc., London*, vol. lxxvii. p. 193, 1921). He shows that the mineral in both perforate and imperforate types is calcite, and that some imperforate species have a vitreous appearance. In the ordinary vitreous foraminifera the shell is composed of minute prisms of calcite set with their longer axes perpendicular to the wall; in porcellanous types, no such regularity is shown by the calcite "fibrils" that are present, and these sometimes pass into a granular structure. Blind canals, but not perforations, occur in the walls of Peneroplis, and it is suggested, from observations by Douvillé, that the alleged perforations of the characteristic Upper Palæozoic genus Fusulina may be of the same nature. The author removes "*Saccammina*" *Carteri* from the arenaceous to the calcareous imperforata, and points out that the mosaic structure of its shell finds a counterpart in Spirillina. He proposes that the genus should now be called *Saccamminopsis*.

CLIMATES OF THE PAST.—In a brief but illuminating review of the climates of past geological periods, Dr. Charles Schuchert (*Amer. Journ. Sci.*, vol. cci., p. 320, 1921) concludes that climatic changes were "very slight during the middle parts of the geologic periods [as defined by faunistic changes], when the world has almost no temperature belts; and variably greatest during the earliest and latest parts. . . . To-day the variation on land between the tropics and the poles is roughly between 110° and −60° F., in the oceans between 85° and 31° F. In the geologic past the temperatures for the greater parts of the periods of the oceans was most often between 85° and 55° F., while on land it may have varied between 90° and 0° F. At rare intervals the extremes were undoubtedly as great as they are to-day." The author believes that for long epochs the greater part of the earth has had an almost uniformly mild climate, with no winters; but he opposes F. H. Knowlton's view that there was a continuous nonzonal arrangement of climate prior to the Pleistocene period. It will be remembered that Dr. Schuchert (see NATURE, vol. cvii. p. 501) connects the limits between geological periods with diastrophic events, and the influence of these, when they are of worldwide importance, is probably effective in breaking up the conditions that tend to equality of climate. In the same journal (vol. ccii. p. 187) Mr. Knowlton replies to Dr. Schuchert, and also to a criticism by Prof. Coleman. He relies on a dual control of temperature in geological times by the internal heat and also by the sun, and believes that the earth was until recently surrounded by a cloud-envelope, maintained by the internal heat, but diminishing from time to time when this heat declined. Few geologists will agree with him in minimising the evidence for the occurrence of occasional epochs of clear air and unchecked sunlight. Surely, moreover, deposits of gypsum are not usually regarded as products of marine lagoons, and the difficulties raised on this matter by Mr. Knowlton seem mostly of his own making. If his cloud-envelope could be regarded as a reality, a good deal of biological as well as physical evidence would have to be reconsidered.

RAINFALL IN LATIN AMERICA.—The United States *Monthly Weather Review* for October 1921 contains articles by Mr. E. Van Cleef and Mr. B. O. Weitz on "Rainfall Maps of Latin America," "Some Illustrative Types of Latin-American Rainfall," respectively. The first article, when dealing with the plotting of the data, mentions that the observations are not always for corresponding periods, and as no correction has been made for this the results are not always comparable, although in drawing the isohyets considerable judgment has been used. The author makes no pretence that the maps give a final statement of the distribution of rainfall, and he states that it may require another 75 years or longer before there is sufficient accumulated data to produce an accurate map. Average maps are given for the year and for the summer and winter. In addition to these there are short accounts explanatory of the rainfall over certain areas, viz. in Mexico, Central America and Panama, and South America. The problem of the *llanos* of Columbia and Venezuela is dealt with, and it concludes with the statement that the cause of the apparent dryness of *llanos* and the absence of trees in interstream areas must remain in the hypothetical stage. The second article is illustrated by graphs showing the annual and monthly averages of rainfall at 25 representative stations in Latin America. The article concludes by stating that the discussion has not covered the complexity of all rainfall types but only those which are most essential. A praiseworthy attempt has been made to associate the climatic controls with various rainfall types.

THE CLAUDE AMMONIA PROCESS.—In the Claude process, in which ammonia is synthesised from nitrogen and hydrogen under a working pressure of 1000 atmospheres, the heat produced in the reaction was at first removed by circulating molten lead round the reaction tubes. This was found, however, to lead to undue strain in the tubes leading to fractures (see NATURE, February 16, p. 219), and a new method has been adopted, an account of which is given by M. Georges Claude in the *Comptes rendus* of the Paris Academy of Sciences for March 6. Uniformity in temperature of the reaction tubes is secured by jacketing them with asbestos or kieselguhr. The heat of combination of the two gases is utilised to heat the entering gas to about 500° C. No preliminary heating is now required, and the tubes are so proportioned that the gases are heated in the catalytic tube gradually as required by the reaction. Among other advantages, the head of the tube carrying the connecting screws is almost at room temperature and the external tube supporting the high pressure is only heated to a high temperature at one end, which can be appropriately strengthened. The method works excellently in practice and has been in use for over twelve months.

University Education in the United States of America.

THE advance sheets of the biennial survey of education in the United States for 1916–18, which constitute Bulletin, 1920, No. 34,[1] contain, in addition to the statistics for the period, an illuminative comparison with figures taken from the reports of earlier surveys which leaves no doubt as to the growth in popularity of higher and university education in America. Exhaustive information is given in the numerous tables, and a number of charts have also been constructed which naturally make a stronger appeal to the eye and emphasise the striking results disclosed by the statistics.

For the year ending June 1918, the Bureau of Education received reports from 672 universities, colleges, and professional schools, the latter term comprising schools of theology, law, medicine, veterinary medicine, dentistry, and pharmacy. Of this total, more than half did not enrol more than 300 students, while of the bigger institutions, only 37 enrolled more than 2000. Thirteen of the latter had from 2001 to 3000 students; nine, from 3001 to 4000; seven, from 4001 to 5000, and eight had more than 5000. Obviously there are many very small colleges and universities and few large institutions. In fact, 10 per cent. of the colleges enrolled 50 per cent. of the students in America and a half of the total number of schools took 87 per cent. of the student populace.

That the tendencies indicated by these figures are not transitory is borne out by Bulletin, 1921, No. 21, on higher education in 1918–20.[2] There it is stated that of 250 institutions supplying returns for the periods 1916–17 and 1919–20, the smallest institutions are showing the biggest percentage increases in enrolment; those enrolling less than 250 in 1910 increased 38 per cent., those with an enrolment of 250-499, 20·2 per cent., those with 500 to 999, 14·5 per cent., those with 1000 to 1999, 22·5 per cent., and those with 2000 and over, 29·4 per cent.

The teaching staff employed in 1917–18 consisted of 29,509 men and 7013 women; *i.e.* an aggregate of 36,522, of which nearly 81 per cent. are men. These figures, when compared with those for the public high schools, in which men constitute 35 per cent. of the teachers, and for the elementary schools, where they form 13·4 per cent. of the staff, show clearly that the tendency is for women to monopolise the elementary and secondary school work while men control the higher institutions. The argument is strengthened by the facts given in Bulletin, 1920, No. 48,[3] on the statistics of State universities and colleges for the year 1919–20, from which it appears that of a total of 13,951 professors and lecturers, 11,659 or 83·6 per cent. are men.

The salaries received by professors and others during the period 1918–20 is discussed in Bulletin, 1921, No. 21, where it is stated that, in privately supported institutions, professors received on an average about 460*l.* per annum and lecturers 240-360*l.*, while in State colleges the salaries averaged 625*l.* and 280-420*l.* respectively. Caustic comment is made on the fact that structural-iron workers and railway employees were receiving more than many assistant professors in private institutions and almost as much as those in State colleges.

The numbers attending universities and colleges have grown from 156,449 in 1890 to 375,359 in 1918, an increase of more than 139 per cent. Enrolment has outstript the growth of population, which has increased from nearly 63 to more than 105 millions, or 68 per cent. increase, but high-school enrolment has increased at an even greater rate. Colleges and universities have not succeeded in attracting, in recent years, so high a percentage of high-school students as formerly. It is thought that the vocational courses now offered by many of the larger high-schools may account for the decrease in the proportion of high-school students who enter the universities. According to Bulletin, 1921, No. 21, an attempt is to be made by the American Council of Education, and a council for education in management composed of representatives of industry, to develop a form of vocational education in the higher institutions which will familiarise men with the technical side of industrial work and also prepare them for managerial positions in industry.

The position of higher education, however, is indicated more clearly by an examination of the enrolment figures in comparison with the proportion of the population which was of college age. From this it appears that in 1898, 3·3 per cent. of the population of age 19-23 years attended college, while for 1916, 4·8 per cent. is recorded. Thereafter is a drop in the percentage, due to the war, but the curve illustrating the figures for the various two-year periods from 1890 onwards shows an unmistakable upward trend. The curve showing the proportion of the population of 23 years of age on which baccalaureate or first degrees were conferred shows a similar steady rise. In 1890, less than 1·3 per cent. graduated; in 1916, almost 2·2 per cent. of this group of the population received first degrees; in twenty-six years, therefore, the proportion of graduates was almost doubled. Moreover, the proportion of the total number of students in the universities and colleges that were graduates increased from 1·5 per cent. in 1890 to 4·3 per cent. in 1916, showing that an increasing amount of time was being spent on what may be termed post-graduate work.

The personnel of the student body has also changed considerably during the past thirty years. In collegiate and graduate departments, the number of men increased from 44,926 in 1890 to 164,075 in 1916, an increase of 265 per cent., and the number of women from 20,874 to 95,436, an increase of 357 per cent. If all the students in all departments are included, these increases are reduced to 143 per cent. and 156 per cent. respectively; in any case, however, it is noteworthy that the number of women students has increased more rapidly than the number of men.

A striking increase has also occurred in the number of first degrees conferred yearly during the twenty-six years ending 1916. For non-professional departments alone, the figures are 7319 for 1890 and 31,826 for 1916, an increase of 335 per cent., while the total population of the United States was increasing by 63 per cent. A graph constructed to compare the rates of increase in the total population and in the number of students receiving baccalaureate degrees from 1870 onwards makes this point very clear. If the number of students receiving first degrees is taken as a criterion of national education, the United States as a nation is undoubtedly becoming better educated year by year. In 1918, there were 28,052 baccalaureate, 3480 graduate, and 736 honorary degrees conferred, while 499 men and 63 women

[2] Bulletin, 1921, No. 21. Higher Education, 1918–20. By G. F. Zook. (Advance sheets from the Biennial Survey of Education in the United States, 1918–20.) 1921. 5 cents.

[3] Bulletin, 1920, No. 48. Statistics of State Universities and State Colleges for the year ended June 30, 1920. 5 cents.

received the degree of doctor of philosophy by examination from 46 institutions.

An attempt has also been made to calculate the proportion of the population which American graduates form. The number of first degrees awarded in 1870–1918 is estimated as 1,058,527, and it is calculated that 908,469 of these graduates were alive in 1918. The total population in 1918 is estimated at 105,253,300, so there was one college graduate to every 116 persons in the country. Taking adults of 23 years and over, the figures become 1 in 61.

The extent of the work undertaken in the colleges and universities is indicated to some extent by the size of their libraries. In 1890, the average number of volumes in a college library was less than 7000. In 1918, this figure had grown to 42,000, while two universities had libraries of more than a million volumes each. The total number of volumes in all the libraries in 1918 was considerably more than twenty-three millions.

The financial position of institutions for higher education in the United States is of interest if only for the sake of comparison with the funds at the disposition of similar institutions in Great Britain. Some of the more outstanding figures have been converted into sterling at the rate of five dollars to the pound, and the results are given in round numbers. Endowments in 1890 amounted to some fifteen million pounds; in 1918, the total was more than ninety-six millions, a similar increase to that shown by the growth in the libraries. During this period, however, the number of students had increased and a better measure of the increase of productive funds is given by comparing the value of such per student enrolled. In 1890, the value was 98*l.* per head and in 1918 it was just over 256*l.*, an increase of 162 per cent. Thus it is doubtful if the increase per head in endowment has really kept pace with the increasing cost of higher education. This statement is borne out by the fact that the percentage of total income coming from endowment funds has steadily decreased during the past 28 years.

The gifts and benefactions reported for the year 1917–18 amounted to just over 5,500,000*l.*; of this amount about 1,100,000*l.* was for increasing plant, 1,000,000*l.* for current expenses, and 3,400,000*l.* for endowments. Thirty-six institutions received gifts of more than 20,000*l.*, and seven of these had benefactions exceeding 200,000*l.* Among these latter were Yale University and the University of Chicago, which received sums amounting to about 570,000*l.* and 420,000*l.* respectively. According to reports for the years 1918–20 received from 317 higher institutions, 27,600,000*l.* was received in benefactions, of which 8,900,000*l.* was for current expenses, 4,800,000*l.* for increase of equipment and plant, and 13,900,000*l.* for endowments. During this period, Harvard University received more than 2,000,000*l.*, Massachusetts Institute of Technology 1,200,000*l.*, and the University of Chicago nearly 1,000,000*l.*, to quote a few of the more noteworthy increases in endowment. These figures, of course, are exclusive of any grants received from Federal, State, or municipal resources.

The value of the property owned by colleges and universities during the period 1890–1918 was ascertained and figures are given for the average value per student. In 1890, this was 108*l.*, while in 1918 it had increased to 279*l.* The property value per student in 1918 was therefore more than two and a half times what it was in 1890, though the fact that the war had reduced the number of students slightly makes the figure for 1918 somewhat high.

The total receipts in 1918 of the universities, colleges, and professional schools in the United States were nearly 30,700,000*l.*, and of this sum about 27,400,000*l.* was reckoned as working income. The corresponding figures for 1892 were about 5,600,000*l.*, and 4,200,000*l.* The average working income per student, however, increased from 14*l.* in 1892 to 73*l.* in 1918; in other words, in 1918 it cost more than five times as much per year to provide education for a student as it did in 1892. Although slightly accentuated by the war, the cost of higher education has been increasing at a steady rate during the whole of this period of 26 years.

The percentages of the total income obtained from the various sources, Federal, State, municipal, students' fees, endowments, and benefactions, also changed considerably between 1892 and 1918. Students' fees have contributed a fairly steady 25 per cent.; the proportion from endowments has decreased steadily from 18·5 per cent. in 1892 to 14·6 per cent. in 1918, while benefactions have, on the whole, also provided a decreasing percentage. Grants from Federal funds increased in general, but the percentage of the total income derived from this source decreased steadily. The State and local authorities have provided a very variable proportion of the income; in 1896, it was only 10·6 per cent., but by 1918 it had risen to 27·2 per cent. Supplementary data for the year 1919–20 are given in Bulletin, 1920, No. 48, which, of course, refers solely to State institutions. The total working income of the 92 universities and colleges which furnished returns for that year was 18,200,000*l.*, of which some 1,800,000 was derived from students' fees, and 1,900,000 from private benefactions. Expressed as percentages, the varying proportions of the total income were contributed as follows: students' fees 9·6 per cent., private benefactions 10·3 per cent., Federal grants 9·0 per cent., State grants 60·6 per cent., and 10·5 per cent. was from miscellaneous sources. The proportion provided by the State is naturally large in State institutions, but the general trend of the figures supports the conclusion reached in Bulletin, 1920, No. 34, that higher education in the United States is coming to depend more and more upon the State or municipality and less on the income derived from productive funds, private benefactions, and Federal grants.

Marine Borers in San Francisco Bay.[1]

AN interesting progress report on the San Francisco Bay marine piling survey has recently been issued by a committee which affords an excellent example of co-operation between science and industry. The Committee was composed of representatives of the American Wood-preservers' Association, the Forest Service, and the Department of Zoology of the University of California, and the necessary funds were contributed by interested parties in the district.

Early in 1914 the activity of marine borers was noticed in the dykes of the Mare Island Navy Yard in San Pablo Bay—the northern arm of San Francisco Bay. The shores of San Pablo Bay have attracted

[1] Report on the San Francisco Bay Marine Piling Survey, prepared under the supervision of the San Francisco Bay Marine Piling Committee of the American Wood-preservers' Association. 1921. Pp. 104+36 plates.

many large industries, the water-front structures of which had been built on untreated piles because it was believed that the discharge into the bay of fresh water by the rivers would prevent invasion by salt water and therefore the advent of marine borers. The attack of 1914 appeared to be sporadic, like earlier ones which had been reported as far back as 1870, but in 1917, at Mare Island, attacks by the same "ship-worm" (Teredo) again occurred, and during the following years spread rapidly and increased in severity. By the latter part of 1919 the attacks had progressed to such an extent that parts of water-front structures, and, in some cases, whole docks, began to fail, and the report of the committee appointed to investigate the problem is now before us.

The marine borers at work in the area comprise the most widely known and most destructive representatives of the groups to which they belong, in addition to one other species which seems to be, as yet, purely Californian. Of the boring molluscs, the first considered is *Xylotrya setacea*, which, when full grown, reaches a length of two feet or more. Details are given of its external features and internal structure. Reference is made to the capacious pouch opening out of the stomach, which serves as a receptacle for the particles of wood rasped off the burrow by the shell. The mechanism of burrowing has been carefully studied, and it is shown that the contraction of the stout, reddish posterior adductor spreads the shell-valves apart and causes their edges to rasp away the wood; the return of the shell-valves to the initial position, ready for the next thrust, is accomplished by the small, weaker, anterior adductor muscle. The shell-valves are not attached to each other by a continuous dorsal hinge (as in the fresh-water mussel), but are widely separated except at two knob-shaped projections which meet in the middle line and serve as fulcra for the rocking movements of the two valves. The cutting action is due to the contact of the anterior face of the shell with the wood and the scraping of this finely ridged edge over the wood by the outward thrust of the shell as the powerful posterior adductor muscle contracts. The shell is held in contact with the bottom of the burrow by the sucker action of the foot. The chips cut away are not more than 0·01 mm. wide, and are several times as long as wide. Prof. Kofoid states that when the borers are active it is possible to hear the rasping of their tools on the wood by placing the ear against the top of the pile.

A short account is given of the life-history of Xylotrya. The eggs are expelled, and fertilisation takes place in the water; the larva forms a velum, develops a pair of shell-valves and a tongue-like protrusible foot. After swimming for about a month the larva, now about 0·75 mm. long, settles down, preferably on wood, and usually near the mud-line. It fastens itself to the wood by a sticky byssus thread, secreted by a gland in the base of the foot, the velum is absorbed, and the foot is transformed into a sucker; the adult type of shell is produced, the elongate siphons are formed, and the animal begins its boring operations. Thirty days after attachment it is about 63 mm. long, and begins breeding, and by the following summer it attains the length of two feet. The largest burrows of this species met with were ⅞ in. in diameter in their lower portions, and more than 30 in. long.

A short notice is given of *Teredo diegensis*, the smallest of the molluscan borers in this area, which was distinguished from other species in 1916. It is only known from the Californian coast, and is of least importance from the economic standpoint.

The well-known "ship-worm," *Teredo navalis*, is considered more fully, as befits its greater importance. This species seems to reach sexual maturity in the first year of its growth. Prof. Kofoid records a heavy death-rate in the autumn, associated with falling salinity of the water, and there is also a heavy death-rate in the crowded territory near the mud-line. The eggs are reported to be retained in the female until they develop into larvæ, which, on liberation, become at once free-swimming. The larva may be carried by tidal currents for long distances, but Prof. Kofoid remarks that, so far as records are available, no evidence exists to show that *T. navalis* has heretofore been found on the Pacific coast; it is, however, only a question of time before this pest will appear in other ports on the Pacific coast. The number of larvæ which may settle on a given pile seems to be limited only by the surface; 437 were counted on a square inch.

Of the three well-known crustacean borers—Limnoria, Sphaeroma, and Chelura—which attack marine structures, only the first two have been found in San Francisco Bay. Limnoria (the gribble) produces few young, but these are not free-swimming, and are ready at once to dig in for themselves. The colony of Limnoria in timber extends peripherally and the burrows constantly deepen. A square inch of Douglas fir heavily attacked by Limnoria was found to contain 79 females, 82 males, and 221 young. Limnoria works at all levels in harbour waters, from near the mud-line to the uppermost tidal level, but is most active between tide-marks, often whittling away the piles to an hour-glass shape. It may be found at work even in the creosoted zone of a pile. Whether it has become slowly acclimatised to the repellent substance or whether creosoting was defective is not known, but Prof. Kofoid states that it is possible, by gradually increasing the strength of the solution, to acclimatise Limnoria experimentally to live and thrive in solutions which originally would have been deadly. *Sphaeroma pentodon* is of small economic importance.

In a general account of the biological indicators of Teredo, Prof. Kofoid points out that, as this mollusc enters the wood as a minute larva and there is only a pin-hole to mark its entry, a close inspection with a lens is necessary to reveal these small openings. But there are other marine animals easily identified and quickly recognised, which may be taken as indicators of conditions suitable for the occurrence of Teredo, and among these he names the barnacle and hydroids, which, from the results of the Californian survey, precede Teredo as part of an invading marine fauna. Their presence, therefore, indicates the possibility of invasion of the area by Teredo, but not the certainty that the latter has arrived. The occurrence of young mussels (Mytilus) on piling is also another danger-sign warning the engineer to look out for Teredo. As the result of the biological inquiry Prof. Kofoid suggests that it is necessary to restrict the uncontrolled use of untreated or unprotected timbers in marine structures, that harbours should not be used as a dumping-ground for waste wood, and that unused infected timber structures should be removed.

In a concluding summary the committee directs attention to certain other practical matters. In those parts of San Francisco Bay where the attack is severe the borers destroy untreated piling in six to eight months, but in other places untreated piling may last two to four years. A life of five to eight years may be expected from paint and batten protections if the work is well done and the covering not damaged by careless handling. Properly creosoted Douglas-fir piling, if carefully handed so that there is no injury extending through the "shell" of treated wood, may last twenty-five to thirty years, but, on account of the damage liable to occur during repeated handling, storage, and rafting, the average length of life has been considerably less. Most of the attacks on

creosoted piling observed by the committee have begun where untreated wood has been exposed by damage in handling the piles, and it is urgently recommended that care be taken to reduce such damage to a minimum. Precast reinforced concrete piles and pile-casings which have been in serv ce for ten years show no evidence of deterioration, and seem likely to be of use for a number of years to come.

Universities of Oxford and Cambridge.

Report of the Royal Commission.

THE report of the Royal Commission on the Universities of Oxford and Cambridge has been published as a Blue Book (Cmd. 1588, 6s. net), and we print below some of the more important recommendations. The Commission, which was appointed in November, 1919, under the chairmanship of Mr. H. H. Asquith, had as its object an inquiry into the financial resources of the Universities and the uses to which they were put, and in this respect the scope of the Commission was very different from those of 1850 and 1877. The immediate occasion for the appointment of the Commission was the application of the Universities for large-scale financial assistance, and the report is confined principally to this aspect of the present position of the Universities.

The first consideration is that the numbers in residence at Oxford and Cambridge have increased largely in recent years and the scope of the work undertaken has widened. As a consequence, the staffs of the Universities and colleges are heavily overworked in many cases and research is suffering. The Commissioners report that either (*a*) the number of students must be decreased, or (*b*) the staffs must be increased, or (*c*) the standard of learning must be allowed to go down.

Dealing with the new relation between science and national development, the conclusion has been reached "that technical education does not suffice. In order to get the greatest scientific results even of a practical character, investigations carried on with merely technical objects and in a merely utilitarian and commercial spirit will not achieve the highest results. The disinterested pursuit of scientific investigation affords the surest means by which the nation can ultimately command the resources of nature." For Oxford, it is suggested that a scheme should be drawn up for future scientific developments in the parks or on some other site near the Museum; for Cambridge, attention is directed to the question of establishing a central institution for training and research in surveying, hydrography, and geodesy. Light and cheaply built laboratories of one storey are also suggested for elementary work.

The financial difficulties which now threaten Oxford and Cambridge are ascribed to their great developments, and also to the change in the value of money. Reviewing possible methods of augmenting the Universities' incomes, the Commissioners are of opinion that raising fees would have the undesirable effect of turning Oxford and Cambridge into rich men's Universities. The real hope of future prosperity and development lies in private benefactions, but unfortunately there is no prospect of private benefactions being obtained sufficiently soon and in sufficient quantity to avert financial disaster. A State grant is therefore recommended, and the Commissioners state definitely that it is an absolute necessity in the public interest that an adequate grant should be made, even under the present financial conditions of the country. The report goes on:—" We recommend that each University receive, instead of the existing interim grant of 30,000*l*., an annual grant of 100,000*l*. a year, in addition to 10,000*l*. a year for special purposes (women's education and extramural work), and a lump sum for pension arrears, in order to enable them to fulfil their functions to the nation in a satisfactory manner."

The principal purposes to which the suggested grant should be devoted are as follows:—proper salaries and pensions for University teachers; the adequate maintenance of the University libraries and museums; the endowment of research and advanced teaching, including more professors, readers, and University or faculty lecturers, and more research studentships for young graduates; the most pressing needs of maintenance in respect of laboratories and departmental libraries; and the provision in both Universities of a Sites and Buildings Fund. The grants should be made to the University and not to the separate colleges.

Of the minor recommendations laid down in the report, a few only will be mentioned. Fellowships are considered to be valuable assets of the colleges, and in consequence the Commissioners recommend that Fellowships be divided into the following classes:—(*a*) Restricted to those who hold certain University posts; (*b*) Fellowships associated with official posts in the College, or with University lectureships or demonstratorships; (*c*) Old Fellows who have retired from active work; (*d*) Fellowships to which young graduates may be elected under conditions of research; and (*e*) Supernumerary Fellowships. (*b*) and (*d*) only should be stipendiary.

Dealing with pensions for members of the staffs of the Universities, the report advocates that the "federated superannuation system of the Universities" be applied, and that provision be made in College statutes for its adoption in all Colleges also, the cost to Colleges being met, if necessary, out of increased fees. It is suggested that the retiring age should be 65 for teachers and administrative officers, and 70 for heads of Colleges.

On the question of the position of women at Oxford and Cambridge the Commissioners express the opinion that ample facilities should be offered for the education of women and for their full participation in the life and work of the University. The Cambridge Committee recommend that women be entitled to be admitted on the same conditions as men to membership of the University subject to various limitations, which include the provision that the offices of the Chancellor, Vice-Chancellor, and Proctor be not open to women.

Finally, it is recommended that any facilities obtained by State grants, directly or indirectly, for the increase of College or Faculty staffs be used to secure more time for research and not to increase the provision for the individual teaching of undergraduates. It is also suggested that a central University Fund be created, assisted out of the general grants from public funds, to enable a specially qualified professor, reader, or lecturer to take a period of absence exceptionally for travel and research, without loss of income, on the recommendation of the proposed Board of Studies and Research. Both these suggestions have been made by the Commissioners with the idea of stimulating and increasing the value of research and advance work.

University and Educational Intelligence.

Leeds.—The chair of civil and mechanical engineering in the University of Leeds will shortly be vacant owing to the resignation of Prof. J. Goodman, who has held the chair since 1890. Prof. Goodman proposes to give his time to research, and the University Council has assigned to him accommodation for this purpose.

London.—Dr. C. A. Pannett has been appointed to the University Chair of Surgery tenable at St. Mary's Hospital Medical School. In 1920–21 Dr. Pannett was Hunterian Lecturer at the Royal College of Surgeons. He is the author of numerous papers on surgical operations and research.

Dr. C. A. Lovatt Evans has been appointed to the University Chair of Physiology tenable at St. Bartholomew's Hospital Medical College. He has carried out research work at the National Institute for Medical Research, at Freiburg, and at Cambridge; and is the author of numerous papers on Experimental and Chemical Physiology.

Dr. G. B. Jeffery has been appointed to the University Chair of Mathematics tenable at King's College. Since 1912 Dr. Jeffery has been Assistant in the Department of Applied Mathematics at University College, and was Acting Head of the Department from 1914 to 1917, in respect of which appointment the Senate conferred on him the title of Reader in Applied Mathematics. He has conducted research work in the Theory of Special Functions, Hydrodynamics, Elasticity, and the Theory of Relativity.

A resolution has been adopted by the Senate expressing great gratification at the establishment by the Worshipful Company of Cutlers of five Scholarships of 90*l.* a year for two years, to be awarded, on the recommendation of the Senate, to suitable candidates who have passed Part I. of the Final Examination for the B.Com. Degree and undertake to enter for Part II. These Scholarships will be "open for competition by young men of British nationality who intend to adopt a commercial, engineering, or metallurgical career, and propose to pursue the study of some foreign language or languages in France or Spain or such other country as may from time to time be approved by the Company."

The following Doctorates have been conferred:—*D.Sc. in Geology:* Mr. L. M. Parsons, an Internal Student, of the Imperial College—Royal College of Science, for a Thesis entitled "Dolomitization in the Carboniferous Limestone of the Midlands." *D.Sc. in Physics:* Miss A. C. Davies, an Internal Student, of Royal Holloway College, for a Thesis entitled "The Minimum Electron Energies Associated with the Excitation of the Spectra of Helium." *D.Sc. in Physiology:* Miss E. E. Hewer, an Internal Student, of Bedford College, for a Thesis entitled "Some Functions of the Suprarenal Glands."

Manchester.—Prof. Arthur Lapworth, who has been, since 1913, professor of Organic Chemistry in the University, has been appointed Sir Samuel Hall professor of Chemistry and Director of the Chemical Laboratories in succession to Prof. H. B. Dixon.

Prof K. H. Vickers, professor of modern history in the University of Durham (Armstrong College, Newcastle), has been appointed Principal of University College, Southampton, in succession to Prof. Loveday, now Vice-Chancellor of the University of Bristol.

Calendar of Industrial Pioneers.

March 30, 1856. Sir William Symonds died.—Entering the Royal Navy in 1794, Symonds at the conclusion of the Napoleonic wars turned his attention to naval construction and in 1825 was permitted to build the brig *H.M.S. Columbine*, the success of which led to his appointment in 1823 as Surveyor of the Navy. During the succeeding fifteen years he was responsible for the design of over two hundred vessels. He introduced various improvements leading to greater speed, more stability, and increased stowage.

March 30, 1882. William Menelaus died.—Trained in Scotland as a millwright, Menelaus rose to be engineer and manager of the Dowlais Iron Works in South Wales, where some of the earliest work was done in connection with the Bessemer process of making steel. He served as President of the Iron and Steel Institute, and in 1881 was awarded the Bessemer Medal.

March 31, 1776. John Bird died.—One of the most famous astronomical instrument-makers of the eighteenth century, Bird began life as a cloth-weaver in the north of England. Coming to London in 1740 he worked for Sisson, and with Graham's assistance in 1745 he set up in business in the Strand. He introduced improved methods of dividing instruments, and supplied mural quadrants to Greenwich and to many of the continental observatories. He also constructed the standard yard measures kept in the House of Commons till destroyed in the fire of 1834.

March 31, 1846. Andreas Kurtz died.—Born in 1781 in Reutlingen, in Wurtemberg, Kurtz as a boy found his way to Paris, where he worked in the factories and gained an intimate knowledge of practical chemistry. After Napoleon's downfall he settled in England, and erected works in Manchester, Liverpool, and St. Helens.

April 1, 1910. Frederick Wicks died.—Known as one of the pioneers in the development of rapid and accurate type-casting and composing machinery, Wicks took out his first patent in 1879, but it was not till twenty years afterwards he achieved success. In 1900 the *Times* was printed from new type supplied fresh every day from a Wicks rotary machine.

April 3, 1667. Edward Somerset, Marquis of Worcester, died.—A zealous adherent to the cause of King Charles I., Somerset after the king's fall resided in France for a time, but returning to England was confined in the Tower. At the Restoration he recovered his estates and then gave himself up to mechanical experiments. In 1663 he published his "Century of Inventions," in which is to be found his plans for a steam pump, "an admirable and most forcible way to drive up water by fire."

April 3, 1871. James Sheridan Muspratt died.—A son of the founder of the alkali industry in Lancashire, Muspratt studied under Graham and Liebig, spent some years on the continent, made various chemical discoveries, and in 1848 established the Liverpool School of Chemistry. He was the author of a standard "Dictionary of Chemistry."

April 4, 1861. Sir James Caleb Anderson died.—Anderson took out several patents in connection with steam navigation and locomotives, and was well known as one of the early experimenters with steam road carriages.

April 4, 1883. Peter Cooper died.—One of the first constructors of locomotives in the United States, Cooper had large engineering works in Baltimore, and was the founder of the Cooper Institute in New York, where some 3000 students are trained in the mathematical and natural sciences.

E. C. S.

Societies and Academies.

London.

Royal Society, March 9.—Sir Charles Sherrington, president, in the chair.—T. R. **Merton** and S. **Barratt**: The spectrum of hydrogen (Bakerian Lecture). The secondary spectrum is characteristic of pure hydrogen and feeble discharges. Impurities weaken it and enhance the Balmer series. The secondary lines are classified in different physically related groups which depend on the pressure of gas, the conditions of excitation, etc. The Balmer series appear in most celestial spectra. There is no evidence of the secondary spectrum in the solar spectrum. Measurements of the widths of the lines by a new method independent of estimates of "limiting visibility" show that the secondary spectrum is due to the molecule. When the current density of electrical discharges through vacuum tubes is great a partial separation of the gases is effected. This may have some bearing on the interpretation of certain celestial spectra. There is much evidence for a specific influence of neighbouring atoms on the spectra emitted. Helium modifies the secondary spectra of both hydrogen and carbon.

March 16.—Sir Charles Sherrington, president, in the chair.—H. H. **Dale** and C. H. **Kellaway**: Anaphylaxis and anaphylatoxins. Guinea-pigs were rendered passively anaphylactic to egg-albumin by injections two days previously of the precipitin for crystallized egg-albumin. Intravenous injection of a further dose of the same precipitin, a few minutes before a dose of egg-albumin, suppressed the anaphylactic reaction. Similarly, isolated plain muscle from anaphylactic guinea-pigs suspended in saline solution, was completely protected from the stimulating effect of egg-albumin by adding to the bath the precipitin which caused the anaphylactic condition. The toxicity of so-called "anaphylatoxins," produced by digesting serum with carbohydrate sols, etc., is due to the formation of complexes which keep the foreign colloid finely dispersed. They do not act on isolated plain muscle, as the anaphylactic antigen does, but are active only in the presence of the circulating blood. Their action is attributed to exposure of the blood to a large foreign surface.—J. C. **Bramwell** and A. V. **Hill**: The velocity of the pulse wave in man. The velocity of the pulse wave, relative to the blood in the vessel, is given in metres per second, $v=3{\cdot}57/\sqrt{\text{per cent. increase in vol. of vessel per mm. of Hg. increase of pressure}}$. An observation of the velocity therefore gives the degree of extensibility of the vessel, and is one criterion of an efficient circulation. It is shown that pressure has a considerable effect on the velocity and that the calculated velocity is less than that observed in man. This is attributed to the "elastic after-action." Experiments on an isolated human artery gave a velocity comparable with that observed in man. The transmission of the pulse wave is purely mechanical, its velocity depending on the extensibility of the vessels as modified by any condition (muscular or otherwise) pertaining at the moment.—A. **Fleming**: On a new bacteriolytic element found in tissues and secretions. A substance termed a "microzyme" found in tissues and secretions is strongly bacterio-inhibitory, bactericidal, and bacteriolytic. It is precipitated from albuminous solutions by protein precipitants, is inhibited by 1/800 normal acid or alkali, and will not pass through a collodion membrane. Filters of porcelain, cotton wool or filter paper absorb microzyme from first portion of fluid filtered, but when saturated the microzyme passes freely. Microzyme affecting *Micrococcus lyticus* is present in most tissues of the human body. Normal urine, sweat, and cerebro-spinal fluid apparently contain none, but tissues of dog, rabbit, and guinea-pig contain microzyme for *M. lyticus*. Egg-white is very potent, showing lytic action at a dilution of 1 in 50 millions, and a small amount was found in the turnip. Human secretions contain microzyme exercising lytic action on most bacteria of the laboratory air, on bacteria pathogenic for animals but not pathogenic for man, and on many cocci isolated from the human body.—J. W. **Pickering** and J. A. **Hewitt**: The action of "peptone" on blood and immunity thereto. Typical inhibition of the coagulation of the blood can be obtained by the addition of "peptone" to blood *in vitro*, in quantities no greater than those required to produce inhibition *in vivo*, provided the disturbance of the surface conditions of the blood, incidental to shedding, is sufficiently reduced. Leucocytes play no part in the anti-coagulant action of "peptone" on blood. The slow injection of maximal amounts of "peptone" into cats, with the liver out of the circulation, produces typical immunity to anti-coagulant action. A physical explanation is suggested. In the interpretation of the coagulation of the blood it is unnecessary to assume the existence of antithrombin, proantithrombin, and antiprothrombin, and current "thrombin theories" become untenable.

Geological Society, March 8.—Mr. R. D. Oldham, vice-president, in the chair.—Baron Francis **Nopcsa**: On the geological importance of the primitive reptilian fauna in the Upper Cretaceous of Hungary. The Upper Cretaceous of Eastern Hungary can be divided into two horizons, the Cenomanian, Turonian, and Lower Senonian strata, and the uppermost Senonian and the Danian formation. The Danian is a freshwater deposit that passes downwards by means of brackish-water beds into the marine strata. The vertebrate fauna of the freshwater beds has, despite its Upper Cretaceous age, a strikingly Jurassic aspect. It contains primitive tortoises, a Camptosaurian Dinosaur, a primitive Trachodon, a Sauropodous Dinosaur, an armoured Dinosaur, and a Pterosaurian. Isolation during the whole of the Cretaceous Period caused a dwarfing of the larger animals (Dinosaurs) but did not affect the smaller forms (crocodiles and tortoises). In consequence of a general uplift at the dawn of the Eocene and the cooling of the climate, nearly the whole of this fauna became extinct. Crocodiles which were adapted to a warm-blooded diet survived until the Miocene Period, and only retired to the tropics when the climate became so cold that the palms vanished from Europe.

Optical Society, March 9.—Sir Frank Dyson, president, in the chair.—T. **Smith** and J. S. **Anderson**: A criticism of the nodal slide as an aid in testing photographic lenses. The nodal slide is only convenient for the examination of lenses over their entire field when these are of normal type unless supplemented by suitable linkages. Collimators and lenses should in general be so directed that all useful light passes through them as symmetrically about their axes as possible.—A. J. **Bull**: A non-polarising spectrophotometer. Uniform monochromatic patches of colour are compared, instead of the more usual arrangement of two portions of a spectrum. The upper half of a spectrum undergoes selective absorption by the material under test, and a region of the spectrum is selected by a slit. A split lens then forms two images of the dispersing prism face which are brought together by a rhomb-like prism with slightly unequal angles. Photometric balance is obtained by

the partial closure of the lower portion of the selecting slit.—J. **Guild**: The photometry of optical instruments. A portable surface-brightness photometer of the polarisation type for the measurement of the fraction of the incident light transmitted or reflected by an optical instrument, and for the measurement of the relative brightness of different parts of a field of view was described. The instrument is a modified Wanner optical pyrometer.—T. **Smith**: A projective treatment of the submarine periscope. The optical events occurring in a periscope may be illustrated by homocentric projection. This affords a simple means of finding the relative advantages of different arrangements of the optical system.—A. J. **Dalladay**: Some measurements of the stresses produced at the surfaces of glass by grinding with loose abrasives. The stresses at the surface of a piece of "greyed" glass were measured and the relation is shown between the size of grains of the abrasive used and the stresses produced.

Linnean Society, March 16.—Dr. A. Smith Woodward, president, in the chair.—C. E. **Salmon**: (1) *Sagina filicaulis* Jord. It differs from *S. apetala* by its tapering sepals, and by their being appressed to the ripe capsule; from *S. ciliata* by being more glandular, sepals less acute, and shorter in proportion to the ripe capsule. (2) *Cerastium subtetrandrum* Murbeck. Occurs in Orkney and in W. Sutherland. It differs from *C. tetrandrum* by being both pentamerous and tetrandrous; the lower bracts are smaller than the stem-leaves, sepal tips are pointed, and seeds smaller. (3) *Arum italicum* Mill. Found in S. and S.W. England, it differs from *A. maculatum* by the petioles being much longer in proportion to the blade, spathes are longer compared with spadix, ovaries more numerous, and the spadix is differently shaped and larger.

Aristotelian Society, March 20.—Prof. G. Dawes Hicks in the chair.—R. F. A. **Hoernlé**: Some byways of the theory of knowledge. In the attempt to give scientific precision to their language, some philosophers have introduced into theory of knowledge a distinction between first-hand knowledge and second-hand knowledge (or knowledge mediated by symbols), alongside of the current distinctions between "knowledge by acquaintance" and "knowledge by description," or "immediate acquaintance" and "thought." Acquaintance and immediate experience are, in current theory, commonly characterised by absence of language and of analysis, whereas first-hand knowledge, *e.g.* a botanist engaged in research, may involve any amount of analysis and symbols. Yet there will be no divorce of description from acquaintance, or of thought from immediate data, but the data will be ordered and acquire significance, and their meaning will come to the investigator as fulfilled and realised, in a sense in which it cannot do so to one who merely reads his account at second-hand. The choice of a terminology is no mere matter of words, for it is a choice of meanings, and therefore of the qualities and relations which we affirm as "true" and "real" of the object under discussion. Definition merely leaves open the question whether anything bearing the character defined exists. The suggestion was made that a comparative and systematic study of philosophical languages is much to be desired as a preliminary to rational choice, and, in any case, as a help to mutual understanding.

DUBLIN.

Royal Irish Academy, February 13.—Prof. Sydney Young, president, in the chair.—S. **Young**: The vapour pressures and boiling points of non-miscible and miscible liquids and the composition of the vapours (distillates) from such heterogeneous and homogeneous mixtures. The formation of azeotropic mixtures of minimum and maximum boiling point was explained, and the case of ternary azeotropic mixtures was especially considered. A large number of these mixtures have been discovered since 1902, and by plotting the boiling points of known ternary and binary mixtures against the boiling points of the aliphatic alcohols it is possible to predict with some confidence whether the alcohols not yet examined will form binary azeotropic mixtures with benzene, normal hexane, or toluene, or ternary mixtures with one of these hydrocarbons and water.

MANCHESTER.

Literary and Philosophical Society, March 7.—Mr. T. A. Coward, president, in the chair.—W. M. **Tattersall**: The sound-producing mechanisms of Crustacea. Some species of Crustacea from the shallow waters and shores of East Africa and others from Australia exhibit mechanisms for the production of sound. Three main types of sound-producing mechanism are found. (*a*) Popping Type: The sound is produced by the rapid withdrawal of a tightly fitting peg from a socket. (*b*) Fiddle and Bow Type. Rapid motion of a sharp smooth ridge or a row of granules across a row or series of rows of regularly arranged granules or tubercles or a file-like series of ridges or *vice-versa* produces the sound. (*c*) Plectrum Type. Two series of stiff, hollow spines are rubbed together. The first type is found in the snapping shrimps (Alpheus) characteristic of coral reefs; the second type in the spiny lobster of British coasts, some shore crabs from tropical waters like Matuta, Platyonichus, Pseudozius and the amphibious crabs, Ocypoda and Uca; and the third type only in certain river crabs in Africa. The stridulating organs occur in both sexes. The sound is probably a warning-note to keep intruders from a burrow already occupied.

Official Publications Received.

Département van Landbouw, Nijverheid en Handel. "'S Lands Plantentuin" ("Jardin Botanique de Buitenzorg"). Treubia. Recueil de travaux zoologiques, hydrobiologiques et océanographiques. Rédigé par Dr. W. M. Docters van Leeuwen, Dr. K. W. Dammerman et Dr. A. L. J. Sunier. Vol. 2, Livraison 1, Décembre. Pp. 155. (Buitenzorg: Archipel Druckkerij.)

Diary of Societies.

FRIDAY, March 31.

Association of Economic Biologists (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—Dr. W. L. Balls: Advantages and Defects of Team Work in Economic Biology.—Dr. F. Kidd: Problems of Fruit Storage.
Institution of Mechanical Engineers, at 6.—Prof. H. H. Jeffcott: The Milling of Screws, and other Problems in the Theory of Screw-threads.
Institution of Electrical Engineers (London Students' Section), at 7.—J. S. Highfield: Presidential Address.
Institution of Aeronautical Engineers (at Royal Society of Arts), at 7.30.—Mr. Folland: Aircraft Design.
Junior Institution of Engineers, at 8.—D. P. Dickinson: The Steel Melting Shop.

SATURDAY, April 1.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: Radioactivity (5).

MONDAY, April 3.

Royal Institution of Great Britain, at 5.—General Meeting.
Royal Society of Arts, at 8.—G. Radcliffe: The Constituents of Essential Oils (Cantor Lectures), (3).
Society of Chemical Industry (London Section), (at Chemical Society), at 8.
Royal Institute of British Architects, at 8.—S. C. Ramsey: London Clubs.

TUESDAY, April 4.

Royal Institution of Great Britain, at 3.—Dr. J. W. Evans: Earth Movements (2).
Royal Society of Arts (Dominions and Colonies Section), at 4.30.—Sir Thomas Bilbe Robinson: New Zealand.
Royal College of Physicians of London, at 5.—Dr. H. Mackenzie: Diseases of the Thyroid Gland (2).
Zoological Society of London, at 5.30.—C. Tate Regan: Exhibition of lantern-slides illustrating Blind Fresh-water Fishes from Caves.—Dr. J. T. Cunningham: Mendelian Experiments on Fowls. III. Production of Dominant Pile Colour.—Dr. M. Khalil: A Revision of the Nematode Parasites of Elephants, with a description of four new Species.
Institution of Civil Engineers, at 6.—Sir Robert A. Hadfield, Bart.: Corrosion of Ferrous Metals.
Röntgen Society (at Institution of Electrical Engineers), at 8.15.

WEDNESDAY, April 5.

Institution of Electrical Engineers (Wireless Section), at 6.—Capt. J. H. Whittaker-Swinton: Provision of Power for Wireless Telegraphy.
Society of Public Analysts and Other Analytical Chemists (at Chemical Society), at 8.—O. D. Roberts and H. T. Islip: The Constants of Indian Beeswax.—A. Chaston Chapman: Note on the Liver Oil of the "Tope" (*Galeus galeus*).—A. Chaston Chapman: Note on the Examination of Foods for the Presence of Sulphites.—S. H. Groom: Demonstration of Artificial Daylight for Laboratory Purposes (Sheringham System).—A. Bruce: A Tropical Milk Supply.—E. R. Bolton and D. G. Hewer: Certain Tropical Oilseeds.
Royal Society of Arts, at 8.—Prof. E. R. Matthews: Sea Encroachment and its Prevention.
Entomological Society of London, at 8.

THURSDAY, April 6.

Royal Institution of Great Britain, at 3.—Prof. A. M. Hind: Landscape Etchers: New and Old (2).
Royal Society, at 4.30.—*Probable Papers*.—F. E. Smith: An Electromagnetic Method for the Measurement of the Horizontal Intensity of the Earth's Magnetic Field.—G. I. Taylor: Stability of a Viscous Liquid contained between two Rotating Cylinders. Part I. Theoretical. Part II. Experimental.—Prof. T. H. Havelock: Dispersion Formulæ and the Polarisation of Scattered Light: with Application to Hydrogen.—Dr. G. R. Goldsbrough: The Cause of Encke's Division in Saturn's Ring.—C. Spearman: Correlation between Arrays in a Table of Correlations.—Dr. W. L. Balls: Apparatus for determining the Standard Deviation Mechanically.
Royal College of Physicians of London, at 5.—Dr. H. Mackenzie: Diseases of the Thyroid Gland (3).
Linnean Society of London, at 5.—Dr. A. B. Rendle: An Example of Regeneration of the Terminal Bud.—C. Turner: The Life-history of *Staurastrum Dickiei*, var. *parallelum* (Nordst.).—L. C. Borradaile: The Mouth-parts of the Shore-crab, with lantern-slides.
Royal Aeronautical Society (at Royal Society of Arts), at 5.30.—L. Brèguet: Aerodynamical Efficiency and the Reduction of Air Transport Costs.
Child Study Society (at Royal Sanitary Institute), at 6.—M. Yearsley: A Plea for the Deaf Child.
Institution of Electrical Engineers, at 6.—J. A. Kuyser: Protective Apparatus for Turbo-Alternators.
Chemical Society, at 8.—Prof. M. O. Forster and W. B. Saville: Constitution of Picrorocellin, a Nitrogenous Constituent of *Roccella fuciformis*.—S. Sugden: The Determination of Surface Tension from the Maximum Pressure in Bubbles.
Civic Education League (at Leplay House, 65 Belgrave Road, S.W.1), at 8.15.—Miss M. M. Barker: Occupational Education.

FRIDAY, April 7.

Diesel Engine Users' Association (at Institution of Electrical Engineers), at 3.—H. Moore: Some Characteristics of Petroleum Oil used in Diesel Engines.
Royal Aeronautical Society (Students' Section) (at 7 Albemarle Street), at 6.45.—Prof. L. Bairstow: Some Aeronautical Problems of the Early Future.
Junior Institution of Engineers, at 8.—J. W. Maple: Engineering in Southern Persia.
Royal Institution of Great Britain, at 9.—Sir Ernest Rutherford: Evolution of the Elements.

SATURDAY, April 8.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: Radioactivity (6).

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

SATURDAY, April 1.

Polytechnic (Regent Street, W.1), at 10.30 a.m.—Prof. H. E. Armstrong: The Wonders and Problems of Food.
Horniman Museum (Forest Hill), at 3.30.—Dr. W. A. Cunnington: Woman's Sphere in Savage Africa.

WEDNESDAY, April 5.

School of Oriental Studies, at 12.—Miss Alice Werner: Bantu Mythology and Folk Lore (6).

The Development Fund.

IN a recent leading article (NATURE, February 16) on the subject of the Geddes Report in its relation to Education and Research, allusion was made to the seemingly precarious condition of the above Fund. While it is a matter for congratulation that the Chancellor of the Exchequer, agreeing with the views which we expressed, rejected the suggestions that the funds provided by Parliament for *additional* research should be used to fill a gap to be created in *existing* expenditure, he did nothing to allay the anxiety created by the depletion of the Development Fund. A White Paper (No. 15, price 3*d.* net) just published contains the accounts of this Fund for the year ended March 31, 1921. It appears that the surplus at the credit of the Fund on that date was 1,170,000*l.*; but of this about one-third represents outstanding loans, and the amount available for current needs on April 1 of last year was only 795,000*l.* Referring to the Report of the Commissioners for the same year we find it stated that "against this balance must be set liabilities . . . in respect of advances recommended up to that date . . . there was a balance, therefore, of 250,000*l.* for annual advances required to meet the *cost of existing* schemes."

The published accounts show that in the year 1920–21 alone advances totalling 568,000*l.* were made, and, so far as it is possible to interpret the accounts, at least 300,000*l.* of this sum was required to meet the recurrent cost of existing schemes. It seems doubtful, therefore, whether the balance available on April 1 of last year was sufficient to meet the normal liabilities of the Fund for the succeeding twelvemonths. There is, however, a reserve not disclosed in the accounts, for in their Report the Commissioners go on to say: "In the estimates . . . for the following year (1920–21) Parliament voted a similar amount [1,000,000*l.*] for the general purposes of the Development Fund. In view of the urgency of restricting issues from public funds, the Commissioners agreed that the grant voted should be surrendered . . . on the understanding that Parliament would be invited to revote the amount in the year 1922–23." But in the statements that have been published from time to time in connection with the economy campaign, this sum of one million has not been specified. It is to be hoped that when Parliament is "invited" to provide the money it will be realised that, without it, the whole organisation of research in the sciences bearing on agriculture and fisheries must collapse.

With the help of the Development Fund a number of research institutions have been established on a permanent basis, and yet there is no guarantee that the money required for their maintenance will be forthcoming even one year hence. Under our Constitution no continuing guarantee can be given, but it might be considered whether greater stability would not be secured by transferring the liability for all permanent schemes to a regular vote head, thus leaving the Fund for real "development" purposes.

The Teaching of Physics.

AT the Orono meeting of the New England section of the Society for the Promotion of Engineering Education held recently, the question was discussed, "What is the matter with physics teaching?" We have received two of the opening papers, from which it appears that in American technical colleges and universities, engineering students dislike and even despise the physics taught them. For this the teacher is blamed, on one hand for not being sufficiently precise and exact in his definitions and reasoning, and on the other for trying to force on the engineer the C.G.S. system of units. Most of the illustrations of bad teaching are taken from dynamics, an accurate knowledge of which is, of course, indispensable to the really scientific engineer.

The trouble is also traced to some extent to the academic text-book, which teems with artificial problems having little relation to what is met with in practice. Students whose minds are gripping the mechanism of water-wheels, pumps, and engines are too often expected to find satisfaction in the study of levers, "simple machines," and systems of weightless and frictionless pulleys. It appears, moreover, that the text-book is being more and more neglected, and, as one writer puts it, "physics has degenerated into interminable class-room coaching, making our teaching

not only very exhausting, but also frightfully expensive, and greatly weakening the *moral* of our students."

There is certainly an element of truth in this criticism. In many universities students get so much direct teaching by lecture, by tutorial expansion, and by the performance of routine experiments to printed orders, that they have little time or energy left for real effective thinking. There is a tendency to forget that a mere knowledge of apparatus and of methods of experimenting does not make a physicist. The physical imagination should be trained, and the highest powers of mind called into play, and the student should be encouraged to get into living touch with the creative literature of the subject. This, of course, is not easy, especially when the classes are large. What is wanted is an accessible reading-room fully supplied with the journals and other publications in which progressive work is recorded. Students, if not overburdened by an excess of class and laboratory attendance, would soon come to appreciate the value and delight of thus getting into touch with the vital problems of the day.

Nevertheless, in the hands of a good teacher there is nothing to compare with the lecture as a means of giving a systematic theoretic view of the whole science treated, and there is no better corrective to the extreme and unscientific utilitarianism which makes many a student think that he is being taught what will be of no value to him. Technical schools may narrow their teaching to what seem at the time to be the absolute necessities, but a university is intended to give engineering students an all-round training in the fundamental sciences of mathematics, natural philosophy, and chemistry. Without these an engineer is only half equipped for his calling.

The Principles of Distillation.

Distillation Principles and Processes. By Prof. Sydney Young, with the collaboration of various authors. Pp. xiv+509. (London: Macmillan and Co., Ltd., 1922.) 40s. net.

THIS book is a new and amplified edition of the author's well-known treatise on "Fractional Distillation," first published in 1903. Prof. Sydney Young is an acknowledged authority on the subject on which he writes, and for many years prior to the appearance of the first edition of his work, the principles underlying the separation of substances by distillation had been investigated by him and the results communicated to various scientific societies. But his book embodied not only his own experience. Everything that was known at that period concerning the science and art of distillation was duly recorded and discussed, and the relative merits of the various still-heads and other forms of apparatus employed in the processes of fractional distillation were carefully inquired into and compared. The rapid development of organic chemistry, pure and applied, during the latter half of the nineteenth century was the immediate cause of the attention which the subject then received. Distillation was practically the only means available for the isolation of the constituents of mixed liquids. The art of distillation is, of course, as old as any chemical process, but the principles upon which its efficient application as a method of separation of complex liquids depend, were very imperfectly understood. Prof. Young's book was the first systematic attempt to explain these principles and to illustrate their bearing upon laboratory and technical procedure. It has not only been of great use to operative chemistry, but it has served to indicate many points of theoretical interest concerning the thermal behaviour of substances which, although they may have no immediate utilitarian value, are certain to influence practice in the future.

During the two decades which have elapsed since the appearance of the first and second editions of this work, a considerable body of additional information has been accumulated concerning its subject-matter, not, perhaps, so much in the elucidation of fundamental principles as in the compilation of accurately observed thermal values upon which the various mathematical formulae which seek to generalise the facts of distillation depend. The present edition differs from its predecessor in one important feature: it deals more particularly with the technical applications of distillation. The book, in fact, is divided into two main sections. The first is practically a reprint of the first edition on "Fractional Distillation," extended and brought up to date by the inclusion of all material facts which have been made known during the last twenty years. For much of this information we are indebted to British workers, and the results of the valuable investigations of Wade and Finnemore and of Wade and Merriman are described in adequate detail. Wade's unfortunate death in the full tide of his intellectual vigour, when all his energies were concentrated upon the development of an inquiry with which by training and aptitude he was specially fitted to cope, was a serious loss to science.

An important addition to the work is a chapter on sublimation. As the author points out, there is no essential distinction between distillation and sublimation, although at first sight the dissimilarity of the two operations would seem to imply a difference. The term distillation denotes the volatilisation of a substance and its condensation and recovery, drop by drop: by sublimation is usually understood the direct passage from the gaseous to the solid state without

intermediate liquefaction. But intermediate liquefaction may be induced by pressure. If, therefore, the process be effected under pressure, liquefaction will occur and the substance will ultimately boil, although on cooling the vapour may pass directly to the solid state. The conditions under which distillation and sublimation become identical operations were first explained by James Thomson, though even now the triple point pressures of only a few substances are accurately known. Indeed, there is ample room for a more extended investigation on the relation of this factor to the other thermal constants of a body. The author describes very shortly a few typical cases of sublimation, such as iodine, sulphur, arsenious oxide, and ammonium chloride, with illustrations of the plant employed, and explains the principles involved in the several instances. As these are not usually indicated in text-books, the attention of teachers may well be directed to them.

The second section of the book, dealing with certain technical and large-scale operations of distillation, occupies about half the volume, and the examples selected for description have been entrusted to chemists with practical experience of their working. They comprise:

(1) Distillation of Acetone and *n*-Butyl Alcohol on the Manufacturing Scale. By Dr. Joseph Reilly and the Hon. F. R. Henley.

(2) Distillation of Alcohol on the Manufacturing Scale. By the Hon. F. R. Henley and Dr. Reilly.

(3) Fractional Distillation as applied in the Petroleum Industry. By James Kewley.

(4) Fractional Distillation in the Coal-Tar Industry. By Dr. T. Howard Buller.

(5) The Distillation of Glycerine. By Lieut.-Col. E. Briggs.

(6) The Distillation of Essential Oils. By Thos. H. Durrans.

These, it will be seen, comprise all the main technical processes with which British chemists, at least, are concerned.

Considerations of space preclude any detailed account of these several sub-sections. The descriptions are such as will appeal to the chemical engineer or works-manager. They are concise, and deal mainly with the practical aspects of the various processes, and the illustrations—chiefly in the form of line-drawings—of the plant employed, will commend themselves to those actually interested in the different industries. There is, as might be anticipated when several writers are concerned with the application of the same physical principles, a certain amount of repetition and overlapping. This is unavoidable, and is not to be deprecated even although these matters are adequately dealt with in the theoretical section of the work. Their restatement, in fact, is required in any adequate account of their bearing upon the particular technical process described.

The book is remarkably free from typographical errors, and we have noticed only a few mistakes—mainly in the spelling of proper names: thus Speyer (p. 29) should read Speyers, and Dufton (p. 138) is erroneously printed Dutton. The work indeed is a credit to all concerned in its production, and well sustains the position it already holds as the chief authority on the subject of distillation. In its present extended form it affords an admirable illustration of the benefits which follow the intelligent application of physical principles to chemical processes on a manufacturing scale.

Mathematical Analysis.

(1) *The Theory of Functions of a Real Variable and the Theory of Fourier's Series.* By Prof. E. W. Hobson. Second edition, revised throughout and enlarged. Vol. 1. Pp. xvi+671. (Cambridge: At the University Press, 1921.) 45*s.* net.

(2) *Introduction to the Theory of Fourier's Series and Integrals and the Mathematical Theory of the Conduction of Heat.* By Prof. H. S. Carslaw. Second edition, completely revised. Vol. 1, *Fourier's Series and Integrals.* Pp. xi+323. (London: Macmillan and Co., Ltd., 1921.) 30*s.* net.

(3) *A Treatise on the Integral Calculus, with Applications, Examples, and Problems.* By J. Edwards. Vol. 1. Pp. xxi+907. (London: Macmillan and Co., Ltd., 1921.) 50*s.* net.

(1) THE first edition of Prof. Hobson's treatise fell naturally into two parts. The first five chapters were occupied with the theory of aggregates, the general theory of functions, and the theory of integration, while the last two dealt with the theory of series, and in particular with Fourier's series. It is the first five chapters which have developed into the present volume. It was inevitable that a great deal of the book would have to be rewritten, for the theory has developed very rapidly; there was a mass of recent research to be incorporated, and much of the older work has been definitely superseded. The preparation of a new edition must have been a very long and heavy piece of work, and Prof. Hobson is to be congratulated on the progress he has made with so formidable a task.

There is a singular contrast between the two great branches of the theory of functions. The complex theory has always been popular. The power of its weapons is obvious; its methods have a striking, if

somewhat illusory, simplicity; and it is fascinating to investigators, to teachers, and to students alike. It is unlikely that the real theory, more abstract and in many ways more difficult, will ever be so generally attractive. Still, times have changed, very largely through the influence of Prof. Hobson himself. The theory is studied seriously even in England, and ignorance of fundamentals is no longer regarded as proof of physical insight or geometrical intuition. Prof. Hobson has every right to be satisfied with his share in this salutary revolution.

It must be admitted that there was some excuse for the conservative mathematician of twenty years ago, and his sneers at a theory which he was too lazy to try to understand. The older theory, the theory of 1900, was not only abstract and difficult, but in some ways really unattractive. There was too little simple and positive doctrine, too many intricate and irritating exceptions. Little could be proved, and the theorems which it was possible to prove were difficult to state in a terse and striking form. The theory of content in particular was obviously imperfect. The theory as a whole seemed dried up and infertile; it is easy to see now how grievously it stood in need of some refreshing storm.

All this has been changed by the rejuvenating influence of the ideas of Borel and Lebesgue. The storm has broken, and the ground has become fresh and fertile once more. There is, indeed, no other region of pure mathematics that has experienced so drastic a revolution. Prof. Hobson's book is the only English book which contains a systematic statement of the revolutionary doctrine, and it is this, above all else, that gives it its unique position.

The importance of the new theories of measure and integration is generally admitted, but their effect on the theory of functions is still very widely misunderstood. They are much more general than the older theories, and it is supposed that, being more general, they must be much more complicated and more difficult to understand. The result is that many mathematicians are too frightened to make any serious attempt to comprehend them. This attitude of panic is based on a complete misapprehension. It is not true that the new theories are much more difficult than the old. It is by no means always the most general and the most abstract that is the most difficult to understand. The trouble with the older theory lay not so much in the inherent difficulty of the subject-matter as in the complexity and clumsiness of the results. The modern theory, in acquiring generality, has acquired symmetry, terseness, and to a great extent simplicity as well. It possesses the æsthetic qualities that are characteristic of a first-rate mathematical science. Its theorems can be stated in a concise and arresting form, and make that appeal to the imagination which enables them to be mastered and remembered. It is much easier to be a master of the new theories than it was to be a master of the old, and it is also much more necessary. A young mathematician who elects to remain in ignorance of them is certain to regret his laziness or obstinacy in years when it is more difficult to learn.

It is, then, Prof. Hobson's chapters on measure (chap. 3) and integration (chaps. 6-8) that are unquestionably the most important in the book. His treatment is much more comprehensive and encyclopædic than that of any other writer. He has three serious rivals, de la Vallée Poussin, Carathéodory, and Hahn. Hahn may be disregarded for the present, as the second volume of his "Theorie der reellen Funktionen," in which the theory of integration is to be developed, has not yet appeared. The works of de la Vallée Poussin ("Cours d'analyse infinitésimale," second and third editions, 1909, 1912, 1914; "Intégrales de Lebesgue, fonctions d'ensembles, classes de Baire," 1916) continue to provide the best introduction to the theory. Between Carathéodory and Prof. Hobson it is unnecessary to discriminate, for both are essential for the systematic study of the subject. It is sufficient to say that there is a great deal in this volume which Carathéodory does not touch.

Chaps. 1, on number, and 4, on transfinite numbers and order-types (chap. 3 of the first edition) have not been greatly changed. We must confess that it has always been this part of the book that we like the least. Prof. Hobson often allows himself to use language which suggests the Oxford philosopher rather than the Cambridge mathematician. "The mind" maintains its position in the first sentence of chap. 1; "objects for thought" are "postulated" on p. 29; a "fundamental difference of view on a matter of Ontology" is mentioned on p. 249. We have an uneasy feeling that if one scratched the mathematician one might find the idealist, and that all these discussions, and especially those which concern the "principle of Zermelo," ought to be stated in a sharper and clearer form.

Chaps. 2 and 3 are concerned with sets of points, the theory of content and measure having very wisely been separated from the descriptive theory. The greatest difficulty is to distinguish the theorems for which Zermelo's axiom is required. We could make some criticisms of detail—we found difficulty, for example, in disentangling the proof that the measure of a measurable set satisfies the postulate (3) of p. 159, tied up as it is with the corresponding proof for

the more difficult postulate (4)—but it would be ungracious to insist on such small criticisms of the most comprehensive presentation of the theory.

In chap. 5, on functions of a real variable (chap. 4 of the first edition), there are very many important additions. The ideas of absolute (p. 276) and approximate (p. 295) continuity are introduced. The treatment of functions of bounded variation (we are glad to find Prof. Hobson now adopting the ordinary language) has been materially simplified, and there is a new section (pp. 318-320) on rectifiable curves. The latter part of the chapter includes an account of some of the most recent work of Denjoy, G. C. Young, and W. H. Young concerning derivatives. Above all, there is a discussion of implicit functions, omitted somewhat unaccountably from the earlier edition. This is a most welcome addition, but we are surprised that Prof. Hobson does not state the fundamental theorem (p. 407) in its most general form. No reference to derivatives is necessary, as was made clear by Young, and a theorem more general than Prof. Hobson's is to be found in so elementary a book as the reviewer's "Pure Mathematics."

Finally, chaps. 6-8 contain the theory of integration, and it is here that we find the most that is new. These chapters are naturally far better than the corresponding parts of the first edition, both in completeness and in logical arrangement, for the first edition appeared at the awkward moment when Lebesgue's ideas were new, and the consequences of his work had not been developed to their conclusion. It may be questioned whether the space (eighty pages) devoted to the Riemann integral is not excessive, since so much of the theory is now of historical or didactic interest only; but Prof. Hobson's object is, of course, to be complete. The importance of the Stieltjes integral is fully recognised in this edition. The last chapter ("Non-absolutely convergent integrals"), dealing as it does with the extreme limits of generalisation of which, in the hands of Denjoy and of Young, the notion of an integral has so far proved to be capable, is very heavy reading; but to have given the first systematic account of these generalisations is in itself a most important achievement.

It is to be hoped that we shall not wait long for the appearance of the second volume, and the completion of a work which has added so much, not only to the personal reputation of the author, but to the status of English mathematics.

(2) Prof. Carslaw's book was conceived on a much less ambitious scale than Prof. Hobson's, but he too has had to rewrite it and turn one volume into two. This first volume contains pure mathematics only, and there is no reference to any physical phenomenon after the introduction. It is, in short, a treatise on analysis, restricted within certain limits, and written with a special end in view.

Prof. Carslaw confines himself quite rigidly and consistently within the limits which he has chosen. It was necessary to have definite limits, but we do not agree entirely with his judgment in selecting them. We think that he has made them too narrow, and that he would have written a still better and more attractive book if he had allowed himself a rather wider scope. It is a very good book even as it is, for it is accurate and scholarly, it contains a mass of most interesting and important theorems which it would be difficult to find collected in an equally attractive form elsewhere, and it is written in an admirably clear and engaging style. It also contains an excellent bibliography of the subject.

Prof. Carslaw has gone too far, however, in his anxiety to eliminate the refinements of the modern theory of functions. For example, the notion of a function of bounded variation is quite explicitly and deliberately excluded (p. 207). The only functions admitted—if we confine our attention, for simplicity of statement, to bounded functions—are those which satisfy Dirichlet's famous condition; they have at most a finite number of maxima and minima within the interval considered. Now there is a serious logical objection to a treatment of Fourier's series in which this class of functions is taken as fundamental, an objection which even a physicist might feel. It is an artificial and not a natural class, since it does not form a group for the elementary operations. Neither the sum nor the product of two functions of the class is in general a function of the class; and it is difficult to see why, if a physicist is interested in two functions, he should not also be interested in their sum.

Prof. Carslaw alludes to the notion of bounded variation as "somewhat difficult," and so, no doubt, it is. But the necessary analysis, as presented, for example, by de la Vallée Poussin, is certainly not more difficult than a good deal which Prof. Carslaw includes. It is not more difficult, for example, than the second mean value theorem, or the theory of Poisson's integral, or Pringsheim's discussion of Fourier's double integral, of all of which Prof. Carslaw gives a very careful account. In any case a book may be made much easier by the inclusion of a difficult theorem, if it helps to elucidate the theorems which the book already contains.

It is inevitable that an analyst, reading a book like this, should be longing to go further all the time. No account of the theory of Fourier's series can possibly satisfy the imagination if it takes no account of the ideas of Lebesgue; the loss of elegance and of simplicity

of statement is overwhelming. We recognise that it would be unreasonable to ask Prof. Carslaw for an account of the modern theories of integration. We hope, however, that, when next he has an opportunity of preparing a new edition, he will remedy the omission which we have emphasised. He should also certainly include the fundamental theorem that the Fourier constants of any integrable function tend to zero (a rather startling omission), and some account of Parseval's theorem. He would thus add greatly to the value of an already valuable book.

(3) Prof. Hobson gives us the mathematics of 1921, and Prof. Carslaw is not far behind him. Mr. Edwards's book may serve to remind us that the early nineteenth century is not yet dead. He directs our attention to "the admirable and exhaustive works of Legendre, Laplace, Lacroix, Jacobi, Serret, Bertrand, Todhunter, etc."; from which he has learnt, for example, that "a limit may be of finite, infinite, or indeterminate value," that "the processes of integration are necessarily of a tentative nature," and that any convergent series may be integrated term by term. Two proofs are offered of the last proposition. In the first it is stated to be valid "provided the series V itself, and the series V formed by the integrations of the separate terms, are both *absolutely convergent*." Mr. Edwards italicises the last condition, but we have no idea why it is inserted, for there is no pretence of making any use of it, nor is its meaning explained.

It is difficult for a reviewer to know what to say about such a book, except that it cannot be treated as a serious contribution to analysis. Twenty years ago it might have been necessary to establish the point in detail; it would be waste of time now, when the battle for accuracy has been won. There is always the danger, however, that a student who reads a text-book may suppose that the statements which it contains are true. We should therefore state explicitly that the "general theorems" asserted in this book are often false, and that, even when they are true, the arguments by which they are supported are generally invalid.

One ought, of course, to judge the book by a different standard, as a storehouse of formulæ useful for instructional purposes. Of such there is an abundance, including a good many which are seldom found in other books, and often entertaining or even important. We may mention Catalan's formula for the surface of an ellipsoid, results concerning roulettes and glissettes, the theorems of Fagnano, Burstall, Graves, MacCullagh, Schulz, and others. The book, in short, may be useful to a sufficiently sophisticated teacher, provided he is careful not to allow it to pass into his pupil's hands.

G. H. Hardy.

Greek and Arab in Medicine.

(1) *Greek Medicine in Rome: The FitzPatrick Lectures on the History of Medicine delivered at the Royal College of Physicians of London in* 1909–10, *with other Historical Essays.* By Rt. Hon. Sir T. Clifford Allbutt. Pp. xiv+633. (London: Macmillan and Co., Ltd., 1921.) 30*s.* net.

(2) *Arabian Medicine: Being the FitzPatrick Lectures delivered at the College of Physicians in November* 1919 *and November* 1920. By Prof. Edward G. Browne. Pp. viii+138. (Cambridge: At the University Press, 1921.) 12*s.* net.

SINCE the great revival of historic interest in the eighteenth century the labour of historians has been directed mainly towards political institutions. Sociological and cultural history have been of much slower growth, and we are only now beginning to be able to treat the history of European life as a whole, to look upon it as one majestic panorama developing from the early Mediterranean culture in which first Egypt, then Crete, then Greece was leader, to the time when Rome herself, in receipt of tributary streams from Syria, Persia, Mesopotamia, and India, acted as the cultural intermediary to the European peoples, and, finally, to the diffusion by those peoples of the infectious elements of the ancient tradition throughout the world. It will thus one day become possible to present this panorama with its various aspects in adequate relation to each other. Mr. Marvin, in his "Living Past," and Mr. Wells, in his "Outline of History," have produced tentative sketches in that direction. Such works point to a time when the history of civilisation, the most absorbing of all topics, will form the humane basis of education. There are, however, large departments in which the material is not yet to hand for this consummation. Especially defective is our record of certain aspects of the development of thought. Formal thought, philosophy, has, it is true, found fairly adequate treatment. A real history of religion is, however, still strangely absent, despite the vast literature which professes to deal with that topic, and the history of psychology is very backward. The history of science, too, presents vast gaps which are sometimes vainly treated as though they represented breaches in continuity of the phenomena rather than breaches in our knowledge, and the two works before us represent the efforts of two eminent scholars in two separate departments to establish continuity across these gaps.

(1) Sir Clifford Allbutt has been distinguished for two full generations and more as an exponent alike of modern scientific medicine and of the scientific

record of Greek antiquity. He brings to this volume, the title of which gives but an inadequate idea of its range, an extent of combined knowledge and experience in these departments that is probably unsurpassed by any other man living.

About half of the book, and this probably the more valuable half, deals with the period of creative activity of the Greek genius. Sir Clifford Allbutt pictures, as perhaps only one of his attainments could, the rise of scientific medicine among the Ionian philosophers of the sixth and fifth centuries before the Christian era, and that process of "separation of medicine from philosophy" which made "science" possible. The earlier philosophers set out to give a picture of the universe both internal and external. They failed because they had not as yet concentrated on the parts which go to make the whole. But their attempt corresponded to an eternal necessity of the human mind. Two and a half millennia have passed. Mankind is now overwhelmed with a vast record in which the details of the parts prevent any vision of the whole. Science, philosophy, and history are each split into a hundred special departments, most of them without adequate relation to the others. Eternal necessity asserts itself again, and the human mind calls for attempts at synthesis. The wheel has turned full circle, and the philosophical, the educational, and the scientific demands of the day echo those needs that Thales sought to satisfy six hundred years before the Christian era.

Sir Clifford Allbutt paints on a big canvas and with the great, sure, sweeping lines that come only to those who have lived a long, full life. His work stands alone in the English language as an attempt to portray, both in outline and detail, the development as a continuous whole of Greek biological and medical thought from its early beginnings to its spread to the confines of the Roman Empire, and to its strange transformation by the new point of view introduced by the decay of the pagan political system and the rise of Christian theology.

This is a high theme which can no more be abstracted by the reviewer than can that of a great epic. The work, like every epic, contains inequalities on which it would be alike ungracious and unnecessary to dwell. But it also contains characteristic and inspiring flashes that often raise it to the level of poetry and make it a real addition to English literature. Not the least characteristic and inspiring of these is Sir Clifford Allbutt's treatment of the idea of inspiration itself and its relation to the ancient doctrine of the *pneuma*.

"To-day," says the author, "as we utter the word *inspiration* we still feel the glow of the spirit which, from the ancient legends of the creation of life to the passages of our modern ethereal telegraphy, from the hauntings of the Great Spirit in primeval man, through the storms of superstition, to the haven of the soul in its purest communion with the Divine, has moulded the whole story of man and embedded itself in his tongue. Yet we shall observe again nevertheless in the history of this, as of all spheres of thought, how a living idea gradually becomes so imprisoned in the letter that its liberty is enthralled in its own formulas. Thus as the brilliant Ionian atomic hypothesis dried up into the arid formulas of the Methodists, as Hippocratean wisdom into Dogmatism, as Empiricism into mere rule of thumb, rational scepticism into Pyrrhonism, so the idea of the pneuma was cribbed in the sectarian Pneumatism."

Sir Clifford will soon be entering his eighty-seventh year, but the vigour of this and many other passages in his remarkable book gives good hope that we may expect much further material from his pen, on topics which he, more than any other living man, is capable of treating with full adequacy.

(2) The learned Sir Thomas Adams professor of Arabic in the University of Cambridge takes up the tale where Sir Clifford Allbutt leaves off. With the fall of the Western Empire Greek science remained in the keeping of the East, and it became progressively orientalised with those changes in the outlook of the Eastern world that may be described as *Byzantinisation*. With the spread of Christianity, and with the advent of schism within the Christian Church, Greek science moved yet further east, and, in its medical aspects, at any rate, was cultivated especially by teachers of the Nestorian sect, by whom much Greek material was turned into Syriac. It was through such oriental versions that Greek medicine passed to the keeping of the Arab-speaking world. The overflow from the Arabian peninsula in the seventh century, and the conquest by the Arabs of the whole of the Near East and the whole of North Africa, the Mediterranean islands, Spain and Southern Italy in the centuries which followed, form one of the most dramatic chapters in world history. The Arabs, great as conquerors and organisers, did not, however, excel in science, and nearly all "Arabian" medical works are the products of men of non-Arab race, Persians, Moors, Jews, and others.

The golden age of Arabian learning culminated between A.D. 750 and 850, the century succeeding the establishment of the Abbasid Caliphate with its metropolis at Bagdad. In the thirteenth century Islamic civilisation suffered an injury from which it never recovered, through Tartar invasion, which destroyed for ever the Caliphate, the unity of the Arabian Empire, and the pre-eminence of Bagdad as a centre of learning. With this fall the hegemony

of the intellectual world passed to Europe mainly by means of material translated into Latin from Arabic, often through Hebrew. This material had itself been largely translated from Syriac, and the Syriac versions themselves were derived from Greek, so that Greek learning reached the West at third or fourth hand. But between the eighth and the thirteenth centuries science and learning, literature and culture remained, like civil organisation and military power, mainly with the Arabic-speaking peoples who stretched from India and Persia to the Atlantic seaboard. The learning of this period is described as "Arabian," and must be carefully distinguished from the true "Arab" material which comes only from Arabia.

It is certain medical aspects of this great Arabian civilisation with which Prof. Browne here deals. It is a subject with a vast literature that can scarcely be treated, even in outline, in a hundred and thirty pages. Apart from the actual changes which the medical system of Greece underwent in Arabian hands, and besides the actual contributions of Arabian authors themselves, an adequate history of Islamic medicine would need to treat of the psychological basis of those changes arising in part from the social and political circumstances of the time, in part from the racial characteristics of the Islamic peoples, and in part from the philosophy and general outlook prevalent among them.

The time is still distant when it will be possible to do this, and Prof. Browne, in this admirable little book, has essayed a smaller task. He concentrates on the work of a small number of the most important Arabian physicians, and notably on three Persians, known to the medieval Latins under the names of Rhazes, Haly Abbas, and Avicenna, whose works were the main carriers of the Arabian medical traditions to the West. Avicenna's enormous "Canon" is especially of importance as being—perhaps with the exception of the "Aphorisms" of Hippocrates—the most widely read work on medicine that has ever been written. More interesting perhaps to most readers will be Rhazes, whose memorable treatise on smallpox and measles was the first in which these diseases were differentiated. This work was translated by the late Dr. Greenhill in 1848, but, with that exception, Prof. Browne's is, so far as we know, the only modern book on Arabian medicine in the English language based on first-hand knowledge. It will be valued both on that account and as a very lucid and scientific exposition of a subject which very few besides Prof. Browne himself are qualified to treat.

(3) *Simple Lessons on the Weather for School Use and General Reading.* By E. Stenhouse. Pp. viii+135 +12 plates. (London: Methuen and Co., Ltd., 1921.) 4*s.*

(4) *Handbook of Meteorology: A Manual for Co-operative Observers and Students.* By J. W. Redway. Pp. v+294. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 24*s.* net.

(1) IN "The Rainfall of the British Isles" Mr. Salter gives a wealth of information that hitherto could be obtained only by searching through the volumes of "British Rainfall." The present work should therefore appeal to the large public which takes an interest in rainfall, and as some 5000 observers read their gauges daily it will be realised how large that public is. Almost every observer would benefit by a perusal of this work, where he will find a discussion of the problems which he himself is assisting to solve. He will find an account of the various types of gauge, and that some, still in use and still sold by instrument makers, are untrustworthy. He will find the exposure of gauges discussed, and he may improve that of his own. He will learn how the data he supplies are used, and find maps illustrating various types of rain, some almost wholly influenced by orographical features, some by the passage of depressions, and others due to thunderstorms.

The discussion of seasonal variation and annual fluctuation will be read with much interest at the present time. Numerous maps are a great feature of the book, and are most instructive; any one who thinks that his own gauge is worth keeping should study the map of the thunderstorm rain in London on June 16, 1917, and note that there was no rain at the Oval, more than $4\frac{1}{2}$ in. at Kensington, while one end of the Serpentine received less than 1 in. and the other more than 3 in.

The rain over the British Isles seems to fall into a watertight compartment; it is perhaps captious to complain that a book on our own rainfall does not discuss the rainfall of the Continent, but it would be of much interest to know how our rainfall links up with that on the other side of the Channel. Possibly the very excellence of the work of the British Rainfall Organization under Dr. Symons, Dr. Mill, and Mr. Salter himself, has made our own information so adequate that it

cannot be compared in full detail with that of neighbouring countries.

There are one or two slips; for example, "right hand rear section" on page 179 should be "right hand front section." The diagram in Fig. 2 is not sufficiently explained to be intelligible to those readers who are not already familiar with the theories of Prof. Bjerknes. The glossary at the end is not very full: we look in vain, for example, for orographical rain and for convection. The book fills a gap in meteorological literature, and the concluding chapter on the economic application of rainfall data is an indication of how widely it should be studied, not only by meteorologists, but also by those outside their ranks.

(2) "Etudes élémentaires de Météorologie pratique" describes the ideal arrangement of stations for a meteorological service, the instruments used, including captive balloons, pilot balloons, and aeroplanes, and the general procedure of such stations. Part 2 is devoted to problems of pressure and wind, and part 3 discusses forecasting. Squalls and thunderstorms come in for full treatment, and also the sudden clearings of the sky, "éclaircies"; the author's experience as chief of the meteorological service of the Armies of the Centre probably led him to study this phenomenon, so important for aviation and hitherto much neglected. The author advocates numerous observation posts, so that a line squall, for instance, may not pass unnoticed between the regular stations of the service. If such a system had been adopted in this country during the war much serious damage might have been avoided at aerodromes in the South of England. The work does not pretend to be a meteorological handbook, but it is valuable for those engaged in official meteorological work, and it discusses interesting points, some of which may still be rather controversial. The chief fault of the work, if fault it be, is that it is unnecessarily full, which would have made an index all the more useful.

(3) Mr. Stenhouse's little book is intended for school students and for the general reader. The subject, including something of dynamic meteorology, is shortly and clearly explained. But there are a number of inaccuracies which ought to be corrected if the work runs into further editions. The coldest time of day is not a little after midnight but a little before sunrise; strato-cumulus is scarcely a combination of stratus and cumulus, nor is cumulus the typical cloud of the middle layer. Alto-cumulus is not even mentioned; and the distinction between cloud sheets and clouds of convection is not brought out. There are some good photographs, but they have not been well selected; snow and frost scenes do not teach anything in particular, and a more typical selection of cloud forms should have been given; the clouds in Plate VI., though given as cumulus, are nothing of the kind; the top picture in Plate VII. has been inverted. The diagrams of sections across weather maps make a misleading use of the term pressure-gradient. In spite of faults, however, the book forms an attractive introduction to meteorology for beginners.

(4) Unfortunately this cannot be said for Mr. Redway's "Handbook of Meteorology," which contains many inaccurate statements. Hydrogen, on account of its lightness, is stated to be thrown off into space by the rapid movement of the earth; air currents "are deflected by the rotation of the earth on its axis easterly in tropical latitudes, and westward beyond the tropics"; the isothermal layer separates the stratosphere and the troposphere; the stratosphere is stated to be radioactive, indicating the presence of electrified dust particles, and the reason why cloud particles remain suspended is stated to be unknown, and electrification is suggested as a possible explanation; these are only a few of the surprising statements to be found in this work.

C. J. P. Cave.

Freshwater Ciliate Infusoria and Heliozoa.

(1) *Etudes sur les Infusoires d'Eau douce.* By Dr. E. Penard. Pp. 331. (Genève: Georg et Cie, 1922.)

(2) *The British Freshwater Rhizopoda and Heliozoa.* By J. Cash and G. H. Wailes. Assisted by J. Hopkinson. Vol. 5. *Heliozoa.* By G. H. Wailes. Pp. vi+72+11 plates. (London: for the Ray Society, 1921.)

(1) THERE is probably no large sheet of fresh water that has been so thoroughly investigated, so far as its fauna of protozoa is concerned, as the Lake of Geneva. Forel, Jean Roux, Penard, and others have shown its richness in variety of form, in the number of species, in cases of parasitism, and in adaptations to other special habits of life. They have set an example which we might well follow in regard to our English lakes, about which we still know so little.

Dr. Penard has already published massive volumes on the Rhizopoda, the Heliozoa, and the Acinetaria of the lake and neighbouring waters, and the present volume on the ciliate Infusoria, not restricted in this case to protozoa of the immediate locality, is no less imposing than the others.

Dr. Penard's work will doubtless meet with a great deal of severe criticism, because his histological methods are primitive and inefficient, his illustrations badly drawn and abominably reproduced, and the arrangement of the text is most inconvenient for the reader. But he disarms criticism, to some extent, as regards the first defect by his frank admission that all his observa-

tions have been made on the living organisms, and that only in certain cases has he used some *intra vitam* stains for special purposes. It is a grievous pity, however, that with such interesting material passing through his hands he has not been able to employ an artist to provide at least a few illustrations of the same delicacy and accuracy as those to be found in the works of Jean Roux. There is not a single one of the three hundred figures that can be said to be a good picture of a living infusorian. They are all crude and inaccurate diagrams.

But these serious defects must not be allowed to obscure the fact that there are recorded in this volume many very interesting and important observations on the natural history of these protozoa. The detailed account, for example, of the explosion of the large trichocysts of *Microthorax haliodiscus*, the description of the conjugation and gemmation of the new Heterotrich *Strombilidium gyrans*, the discovery of the formation of small copulation buds in Cothurnia, and many other records of the author's observations are really valuable contributions to knowledge, and suggest at any rate interesting lines of research for some one who can use more modern methods of technique.

Dr. Penard proposes to add to our lists the names of several new genera and many new species; but it seems very doubtful if these new genera and species can be established until a better and more trustworthy account of the nuclei and other details of structure can be provided. Any one who has had experience of investigations of these active minute organisms must be aware of the uncertainty of observations on the form and structure of the meganuclei that are made when the animals are still living. Such observations must be confirmed and extended by a study of properly fixed and stained preparations before they can be regarded as trustworthy. More particularly is this the case with the micronuclei, which are usually quite invisible during life and require the best technical methods for their complete elucidation; and we may note, in this connection, that the author does not mention either the sixteen micronuclei of *Bursaria truncatella* or the single but remarkably conspicuous micronucleus of *Spirochona gemmipara*.

In a group of animals such as the Ciliata, which possess so few trustworthy characters for systematic work and vary so much as regards these characters according to environmental conditions, the systematist should not be satisfied with his description of new species until every important character that can be seen by the ordinary methods of research has been seen and described. If microscopists pass from the description of one species of Ciliata to that of another before the nuclear structures of the first have been determined, as Dr. Penard has done, our literature, already overburdened with unnecessary specific names, will soon become most hopelessly perplexing and cumbersome.

Dr. Penard's work will be useful for reference, and perhaps suggestive of lines for further investigations by other methods of research, but it cannot be regarded as one that excites great confidence.

(2) The new volume on the freshwater Heliozoa of the British Isles published by the Ray Society gives a record of genera and the species that have been found by microscopists in this country who have been interested in the group, but it does not do justice either in text or plates to the important morphological features or to the beauty of form that these remarkably interesting protozoa possess.

It is very disappointing that in this monograph the general account of the structure and reproduction of the Heliozoa is so incomplete. For example, in the very slight treatment of the reproduction of Actinophrys and Actinosphærium there is no reference to the works of Schaudinn or R. Hertwig. It seems extraordinary also that those who are responsible for the publications of the Ray Society have no better methods to suggest to the young microscopist for the preservation of these delicate organisms than 5 per cent. carbolic acid, formalin, and methylated spirit, and that no methods at all are given for staining preserved specimens to bring out more clearly the structure of the nuclei and other minute details.

The purely systematic part of the work is more satisfactory, and the microscopist will find a short but clear description of all the species that have been recorded in this country with references to many of the more important papers in the literature of the subject. Of the eighteen text-figures only two seem to be original, the others being either reproductions of the coarse and lifeless illustrations in Penard's monograph or taken from other authors. Figures such as these, in which the detailed structure is not clearly or accurately shown, do not incite to careful and patient study, although they may assist to some extent in the identification of species. The illustrations in the plates also, with a few exceptions, are far below the standard we might reasonably expect in the publications of the Ray Society. They do not represent these beautiful little organisms as spherical in shape with radiating pseudopodia on the whole circumference, but rather as flat discs with the pseudopodia in one plane.

Another fault which seems to be unpardonable in a work of this kind is the failure to give any description or descriptive lettering of the figures to assist the reader. In such a figure as that on p. 44, for example, it is impossible to determine which of the several circles in the endoplasm of Pompholyxophrys is the nucleus and what the other things are supposed to represent. And again,

in the illustrations of *Actinophrys sol* on Plates 67 and 72 there is no explanation of the different forms of the body and its pseudopodia that are represented. A few lines on the opposite page giving the reason why six different drawings of this one species are shown on the first of these two plates would have added immensely to the value and interest of the account of the species.

Our Bookshelf.

Organic Syntheses: An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. 1. Pp. viii+84. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 8*s*. 6*d*. net.

In preparing materials for use in research work in organic chemistry, much difficulty is experienced and time wasted because adequate directions are not available. Moreover, the methods finally adopted are not often published, so that the work involved in discovering how to make the preparation successfully is lost, and may be repeated indefinitely in different laboratories. The present volume is the first annual instalment of a record of methods of proved merit, given in sufficient detail to ensure easy repetition; the methods given have been tested by being carried out from the instructions in a different laboratory from that in which these were drafted. The substances dealt with in the first volume are alkyl bromides, allyl alcohol, benzinesulphonic chloride, benzil, benzilic acid, benzoin, α-bromonaphthalene, *p*-bromophenol, diacetone alcohol, furfurol, mesityl oxide, methylene iodide, methylhexyl carbinol, oxalic acid, thiophenol, trimethylamine, and trimethylamine hydrochloride. In future volumes it is hoped to include preparations worked out in other countries and tested by repetition in one of the four American laboratories which are responsible for the organisation of the scheme.

The preparation of materials such as these in quantities of from 200 to 2000 grams offers a unique opportunity for determining their physical constants by exact methods, *e.g.* a determination of freezing points to 0·01° by means of a standardised thermometer recording the temperature of 100 grams or more of purified material, instead of to about 1° by the use of a milligram of material in a capillary tube attached to a thermometer of unknown errors. This useful development of the work may perhaps be looked for in the later volumes of the series.

T. M. L.

Exploitation du Pétrole par Puits et Galeries. By Paul de Chambrier. Pp. 106. (Paris: Librarie Dunod, 1921.)

In February 1921 a paper was read before the Institute of Petroleum Technologists on the working of petroleum by means of shafts and galleries, being an abstract from a pamphlet entitled "Exploitation du pétrole par puits et galeries," written by Prof. Paul de Chambrier. This pamphlet has recently come to hand, and it discusses at some length the methods employed more particularly at Péchelbronn, Alsace, in a bold attempt made to extract oil from certain horizons already exhausted by the drill.

The publication of the paper in this country created very considerable interest and even controversy at the time, and opinion was much divided as to the possibility of extending such methods to other fields. The pamphlet in its original form, however, makes most interesting reading, and there is no doubt that under certain specialised circumstances recourse may be had to this form of mining petroleum with decided probability of success. Such circumstances occur when (1) the producing bed has been drained so far as boring permits, (2) when there is an absence of gas under pressure, and (3) when the percentage of oil remaining in the bed is high enough to warrant the attempt being made. One may add a further condition, namely, that the bed does not lie at too great a depth from the surface.

The author contends that these methods allow the extraction of anything from two to five times the amount of oil obtainable by boring, and their ultimate employment, where possible, considerably enhances the economic value of the property. While these contentions may be quite justified commercially, it is open to doubt whether, from the scientific point of view, this practice will yield solutions to the fundamental questions of origin, migration and accumulation of petroleum, as indicated in the concluding paragraphs, but we recommend the careful perusal of the pamphlet before adverse criticism of this new departure be indulged in by either academic or technical expert.

H. B. Milner.

The Chemistry of the Garden: A Primer for Amateurs and Young Gardeners. By H. H. Cousins. Macmillan's Primers. Revised Edition. Pp. xxxi+147. (London: Macmillan and Co., Ltd., 1921.) 2*s*. net.

The new edition of Mr. Cousins's well-known little book will be welcomed by all who are interested in their gardens. In spite of the vast number of gardening books and the fact that it was first written twenty-three years ago, this book still remains one of the most useful guides that can be put into the hands of the amateur. Horticultural research does not move very quickly, and there has been less necessity for recasting than if the book had dealt with agriculture. Fuller investigation would no doubt cause modification in some of the recommendations made, but until it has been carried out the advice stands as the safest that can be given at present. Above all, its basis is sound. "I appeal," says the author, "to the gardeners of England to place themselves in line with the only true and sound method known to science, and the only safe and sure means to progress and discovery—experiment."

A Course of Practical Physiology for Agricultural Students. By J. Hammond and E. T. Halnan. Pp. 106. (Cambridge: At the University Press, 1920.) Price 4*s*. 6*d*. net.

This small book, which is not illustrated, contains exercises mainly in elementary histology for second-year students taking the course in agriculture at the University of Cambridge. Space is afforded for notes and drawings. The book will save time and labour for both student and teacher without disadvantage, as it does not pose as a text-book.

Letters to the Editor.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.*]

Atmospheric Refraction.

I perceive on further consideration that my suggestion (Nature, January 5, p. 8) of a spherical wave-front in place of a plane one to account for the discrepancy between the coefficient of terrestrial refraction as derived by Dr. Hunter from Mr. Mallock's proposition and the coefficient deduced from trigonometric levelling operations under ordinary conditions is inapplicable, for the reason that in practice we have to deal, not with a single point-source of light, but with an assemblage of point-sources the wave-front from which is sensibly plane.

There must, therefore, be some other explanation for the disagreement between the two values of the coefficient. I find on examining Dr. Hunter's figures (Nature, August 11, 1921, p. 745) that the almost exact two-to-one ratio between the values, which was suggestive of a simple geometrical explanation, is illusory owing to an unfortunate slip of Dr. Hunter in confusing sea miles with statute miles. The earth's radius in sea miles is not 3960, but 3437, and the resulting value of k from Mr. Mallock's proposition is not 0·133, as Dr. Hunter states, but 0·116. Using the Continental definition of k, this gives $k=0{\cdot}232$, which agrees with the value found by Jordan's formula (quoted in my former letter) for isothermal conditions at 0° C. As to the remaining discrepancy between 0·116 or 0·232 and the values of k (on the two definitions of it) which are usually found to hold in practice, it is clear both from Comdr. Baker's letter (Nature, January 5, p. 9) and from Jordan's formula that this is readily accounted for by temperature considerations. It is only under isothermal conditions, such as seldom or never occur in practice, that Mr. Mallock's result can be even approximately true; it was evidently incorrect to consider, as Mr. Mallock did in his reply to Dr. Hunter, that temperature effects could produce merely a difference in the result of 1 or 2 per cent. per 1000 ft. The mistake of assigning an insignificant part to temperature considerations is one which is very easily fallen into by any one who first considers the isothermal condition with its accompanying relation between density and pressure, because of the small effect which the existence of a temperature-gradient has on the rate of decrement of pressure as distinguished from density.

The great interest of Mr. Mallock's demonstration lies in its deriving the refractional radius under certain conditions in a very simple and elegant manner from the velocities of light in air and *in vacuo* and the height of the homogeneous atmosphere. What has led to some confusion is the omission from the enunciation of the proposition of the qualification that it holds true only for isothermal conditions and for air at 0° C.

Putting p for pressure, ρ for density, and h for height, we may take the refractional radius as depending only on dp/dh, as Mr. Mallock does, so long as we keep to isothermal conditions. But once we depart from these conditions, as is inevitably the case in practice, we must take it as depending on $d\rho/dh$, which no longer corresponds to dp/dh. We can, however, extend the simplicity of Mr. Mallock's reasoning to the condition of a linear temperature-gradient provided we replace the height of the homogeneous atmosphere, $-pdh/dp$ (or "pressure height," as Prof. Everett preferred to call it in his "C.G.S. System of Units"), by the "density height," $-\rho dh/d\rho$, which latter may be much greater than the "pressure height" under ordinary conditions.

Comdr. Baker lays great stress on the fact that the path of the refracted ray cannot be a circular arc unless the temperature-gradient is linear. This stress is justifiable, especially from the seaman's point of view of the problem; for the temperature-gradient in the air immediately over the sea is frequently far from linear, and in navigation horizontal sights must always be taken fairly close to the surface of the sea; moreover, it will seldom happen that the most favourable time of day can be chosen for observations at sea.

The moral is that in navigation too much reliance should never be placed on the results of observations made on a single bearing whenever the accuracy of the tabular value of the dip has to be assumed. But the land-surveyor is much less limited by conditions than the seaman; he can generally keep his lines well above the ground by observing between points of considerable elevation, he can choose that time for his observations when refraction is least likely to be abnormal, and he can usually get an adequate check on his results for the elevation of a point by observing it from a number of others at different distances and comparing the results. As a matter of experience, it is found by surveyors in many countries that during the afternoon hours, when refraction is steadiest, the assumption that the temperature-gradient is linear and the path of a nearly horizontal ray consequently a circular arc is tolerably near to the truth, at any rate for lines which do not run very close to the ground for any considerable part of their length. This follows from the close concordance between the trigonometric levels obtainable for the same point from stations at very different distances, when the observations have been taken under proper conditions and worked out by the usual formulæ.

John Ball.

Survey of Egypt, Cairo, February 11.

Diffraction by Molecular Clusters and the Quantum Structure of Light.

The investigations on the molecular scattering of light now in progress under the writer's direction (regarding which previous communications have been published in Nature) have brought to light some very remarkable cases in which the observed facts are in sharp contradiction with the theories of light-scattering based upon Maxwell's electromagnetic equations. According to the Einstein-Smoluchowski formula for the scattering power of a fluid, viz.

$$\frac{\pi^2}{18}\frac{\mathrm{RT}\beta}{\mathrm{N}\lambda^4}(\mu^2-1)^2(\mu^2+2)^2,$$

the intensity of the diffracted beam should be proportional to the compressibility β of the fluid and should thus be very large near the critical temperature as the compressibility is there great. Experiments by Keesom and Kammerlingh Onnes have confirmed this result in the case of ethylene vapour over a range of a few degrees above the critical temperature. The scattering powers of liquid carbon di-oxide and vapour for a considerable range of temperatures below the critical point have been determined in the writer's laboratory by Mr. K. R. Ramanathan, who has discovered that the formula is approximately valid only for a range of a few degrees below the critical temperature, and then

falls off much more rapidly than according to the formula. These observations are significant in view of the observation by the present Lord Rayleigh that the scattering power of saturated carbon di-oxide vapour at 21° C. is only 102 times that of the gas at atmospheric pressure, whereas according to the Einstein-Smoluchowski formula, it should have been 855 times as great.

The failure of the formula indicated above is especially surprising in view of its successes in other directions, namely, in the case of gases obeying Boyle's law, in the case of liquids under ordinary conditions, and, with certain restrictions, even in the case of solids. In attempting to find an explanation of the failure, at first sight one naturally seeks to find some flaw in Einstein's theory, or in the application of it, but the very successes of the formula in other cases would tend to discourage such an attempt. The formula was deduced by Einstein by applying Boltzmann's principle of entropy-probability in order to find the magnitude of the fluctuations of density of the fluid arising from thermal agitation and deducing the light-scattering due to these fluctuations by application of Maxwell's electromagnetic equations. It is clear that density fluctuations due to thermal agitation must occur; that their magnitude is proportional to the square root of the compressibility of the medium as contemplated in the theory may be confirmed independently by identifying the thermal energy of the molecules with the energy of sound-waves of all possible wave-lengths in an enclosed volume of the fluid and equating the energies. Further, the idea that the non-uniformity of the density of the medium is the factor determining light-scattering, at least according to the wave-theory, is confirmed by the very complete analysis of the problem given by the late Lord Rayleigh in one of his final papers (*Phil. Mag.*, Dec. 1918, p. 449). How, then, are we to escape the difficulty?

A very luminous suggestion made by Jeans in his "Dynamical Theory of Gases" (page 203) is here of great help. Jeans distinguishes between two kinds of clustering in fluid media, *mass-clustering* and *molecular-clustering*, and points out that they tend to become identical at the critical temperature. Einstein's theory is based on the idea that the fluctuations of density and the resulting scattering of light are both due to *mass-clustering*. If, however, we assume that it is *molecular-clustering* that is of importance and results in an increased scattering of light, it is easy to see that in the case of molecules such as carbon di-oxide, which are ordinarily non-associated, the clustering of molecules would only be appreciable near the critical temperature, and that at lower temperatures the clusters would rapidly break up and resolve themselves into single molecules. A double molecule would scatter four times as strongly as a single molecule, a triple molecule nine times as strongly, and so on, and if we assume that the energy-effects of separate molecules or groups are additive, and calculate the number of associated molecules from thermodynamic principles, it is easy to give the theory quantitative expression and explain the increased scattering near the critical point, and the rapid fall at lower temperatures.

But the fundamental difficulty remains, why the *mass-clustering* considered by Einstein does not, as it should, according to the classical wave-theory of light, give rise to an increased scattering of light?

To the present writer, at any rate, it appears that this contradiction of the electromagnetic theory by experience may have to be classed with its other known failures in the theory of photo-electricity and other modern fields of inquiry. We may, in fact, have to adopt the quantum theory of the structure of light as propagated in space (and not only when it is absorbed or emitted) in order to explain the facts of molecular diffraction. Fuller experimental data which are now being obtained in the writer's laboratory may pave the way towards the clearing up of this fundamental question.

C. V. RAMAN.

210 Bowbazar Street, Calcutta, March 2, 1922.

The Radiant Spectrum.

PROF. RAMAN in his reply of February 9 to my criticism of his first letter of September 1, does not refer to the fundamental difference of opinion between us. For it was the statement "the phenomenon is due to diffraction by the corneal corpuscles," to which I took exception, because I could not find in his letter, or in Brewster's paper, any evidence on which such a conclusion could be based.

With regard to the corneal corpuscles, Schafer writes in his "Essentials of Histology" (p. 363, edition 6), "Between the laminæ (of the cornea) lie flattened connective tissue corpuscles, which are branched and united by their processes into a continuous network; there is, of course, a corresponding network of cell spaces." Since, then, the corneal corpuscles lie within the substance of the cornea, their optical effect will depend on their opacity to light, or on the difference between their refractive index and that of their surroundings. Now if there was opacity, or a difference in refractive index, they should be visible under the microscope. But such is apparently not the case. Staining with hæmatoxylem or some other suitable reagent, is necessary in order that they may be visible, and therefore their opacity, or difference in R.I., must be slight. We conclude, therefore, that they will cause but slight diffraction in a ray of light passing through the cornea. In shape the cells themselves are *highly* irregular, and they average in man 20-30 μ in diameter. Their nuclei in man are roughly oval in shape, about 16 μ in diameter. In order that these structures should produce the type of diffraction pattern described by Prof. Raman, there should be two sets of them, nearly circular in outline, with diameters of 13 μ and 7 μ respectively. But a further point arises: Prof. Raman describes slight relative movements on the part of the diffraction pattern, which he compares with those which occur when a film of milk on glass is held in front of the eye. This movement, he states, ceases if the eyelids and eyeball be kept motionless for a short time. Could the corneal corpuscles undergo this movement lying as they do in lacunæ in the substance of the cornea? And even if they could, why should their motion cease when the lids and eyes are kept still?

Not only has no evidence been advanced by Prof. Raman in support of his statement that the corneal corpuscles are responsible for the diffraction phenomena, but also the shape, size, situation, and optical properties of these structures would appear to be antagonistic to the view.

With regard to the scattering of light by a prism, the following experiment will be found to demonstrate the effect. On the bed of a spectrometer are placed, base to apex, two glass prisms of equal dispersion, with optically good and clean surfaces (see Fig. 1).

narrow vertical strip of black sheet-metal or cardboard is fixed across the mouth of the telescope with plasticine, and the telescope is adjusted until the bright image of the slit is completely obstructed. On looking past the strip towards the prisms the observer will see parts of the latter brilliantly lit. By slightly shifting each prism in turn and watching for movement in the bright specks, those due to each prism are readily identified. H. Hartridge.

Land Snails of the Madeira Islands.

In 1892 (*Journal of Conchology*, vol. vii. No. 1) the Rev. R. Boog Watson published a very interesting discussion of the Madeira snails, in which he raised many questions concerning their origin and history, which he did not attempt to answer. To-day, we are still groping for light, but I believe we may reach a number of conclusions which are not likely to prove erroneous.

(1.) It is not true that the numerous endemic snails of the islands have come "without trace of descent." They are quite clearly of Palæarctic origin, and their ancestors may be looked for in the rocks of Europe. Among the European Tertiary fossils, *Plebecula ramondi* Brong., from the Miocene of Germany, resembles the Madeira and Porto Santo Pleistocene fossil *P. bowditchiana*; *Pseudocampylaea insignis* Klein, from the Miocene of Würtemberg, resembles the great *P. lowei* of Porto Santo, but is not so large; two species of Craspedopoma, apparently allied to Madeira forms, are found in the Eocene of France. These fossils may be seen in the British Museum. In the absence of anatomical evidence, the relationships of these fossils must remain somewhat uncertain, but it is at least probable that their apparent affinity with the Madeira snails is not wholly deceptive.

(2.) Considering the diversity and strong peculiarities of most of the Madeira species, it is unlikely that their ancestors arrived later than the beginning of the Tertiary, and it is not improbable that at least part of the immigration dates from the Upper Cretaceous. This postulates a greater age for the islands than our present geological information can confirm. According to this view, the European fossils are presumably not the actual ancestors of the Madeira fauna, but derivatives from the same general stock.

(3.) A comparison between the snails of Madeira and the adjacent island of Porto Santo, which is easily visible from the coast of the larger island, shows that we have two very distinct faunæ, with very few species in common. More than this, various genera or subgenera are restricted to one of these islands, or specially characteristic of one. It is, I think, quite certain that during the whole long history of the snail fauna, Madeira and Porto Santo were never united. On the other hand, everything indicates that the three Desertas were during Tertiary time joined together and continuous, or nearly continuous, with Madeira. The following facts are illustrative:

Pseudocampylæa. Two species, Porto Santo only.

Cryptaxis. Three species, Madeira and Desertas (Leptaxis differs anatomically, as I shall show elsewhere).

Katostoma. Several forms, Porto Santo and adjacent islets.

Lampadia. One species, Porto Santo. (The Madeiran *membranacea* does not belong here.)

Idiomela. One species, Porto Santo.

Hispidella. One species, Madeira.

Lemniscia. One species, Porto Santo. (I am satisfied that the Madeira *calva* and *galeata* are not related.)

Actinella. Five species, Madeira and Desertas.

Hystricella. Seven species, Porto Santo and adjacent islets.

Geomitra. Seven species, Madeira and Desertas.

This list could be extended, but it is, I think, sufficient to indicate, not only that Madeira and Porto Santo were not united, but that they were never united with the mainland. The diversity of the genera and subgenera on the two islands might be expected as the result of accidental colonisation at very rare intervals, but could scarcely result from the breaking up of an originally homogeneous fauna. If we employ the aggregate genera Leptaxis and Geomitra (properly Ochthephila Beck, which is not preoccupied) without subdivision, the actual facts are obscured.

(4.) Nevertheless, we have to account for the occurrence of a certain number of identical species in the two islands, and the fact that some of the groups, such as Discula, are well represented on both islands, with closely allied species. The identical species were not introduced by man, as they occur fossil in the Pleistocene of Caniçal. As a general rule, when a group has representatives on both islands, it appears to be primarily or primitively a Porto Santo group. An apparent exception is Callina, with four Madeira species and one (*rotula*) in Porto Santo. The species *rotula* is very peculiar, and probably should not be associated with the others. How these various snails or their ancestors crossed the 23 miles from one island to the other is unknown. Some may have been carried by birds, possibly some may have come on floating pumice or other floating objects.[1] The reason for the apparent tendency of Porto Santo types to reach Madeira, rather than the reverse, may be found in the fact that the arid eastern end of Madeira is well suited to Porto Santo species, while Porto Santo is unsuited to the species from the moister uplands or coasts of the greater part of Madeira.

(5.) The occurrence of well-defined species and subspecies on the islets around Porto Santo—some of them no larger than a large building—proves that no important oscillations of level have taken place in recent geological time. Very moderate alterations of level would submerge the islets, or unite them with the main island. The existence of these distinct forms on islets close to the main island also proves that the means of crossing the sea, whatever they are, operate at extremely infrequent intervals.

(6.) With regard to the species of the Madeiras which are actually identical with those of Europe, it must be said that the presumption is in nearly every case that they were introduced by man. It is possible, however, that some of the smaller ones were brought by "natural" means in geologically recent times, and highly probable that Balea was so brought to Porto Santo, on the feet of birds. Records of the occurrence of European species in the Pleistocene deposits of Madeira and Porto Santo all break down on critical examination.

That the islands are really "oceanic" is indicated by the total absence of indigenous mammals (except bats) and amphibians, and the general character of the invertebrate fauna and of the flora. The multitude of snails has seemed to suggest a former land connection, but I now believe that the snails themselves negative this view. T. D. A. Cockerell.

University of Colorado, Boulder, March 2.

[1] Experiments should be made to determine whether it is even possible for snails protected by epiphragm or operculum, to pass alive through the alimentary canal of birds. Compare Wallis Kew, "The Dispersal of Shells," p. 45.

Optical Rotatory Dispersion.[1]

By Prof. T. M. Lowry, F.R.S., and Dr. P. C. Austin.

1.—*Introduction.*

The discovery of optical rotatory dispersion may be said to have preceded rather than followed the discovery of optical rotatory power, since it was the unequal rotation of the plane of polarisation of lights of different wave-lengths which gave rise to the sequence of beautiful colours which Arago described in 1811 as being produced by the interposition of quartz plates between a polariser and analyser set to extinction. These colours were shown by Biot in 1812 to be due to a rotation of the plane of polarisation which increased with the thickness of the quartz plate and with change of colour from red to violet. When, therefore, a beam of polarised light had passed through a quartz plate it was impossible any longer to extinguish all the colours simultaneously with any one setting of the analyser.

Two features of Biot's work deserve special attention. In the first place, all his measurements of optical rotatory power included observations of rotatory dispersion; the custom of observing the rotatory power of a substance for light of only one wave-length and thus recording a single point on a curve of unknown form is of comparatively recent origin, and marks a distinct retrogression from the more thorough methods of the earlier workers. The second characteristic was the exact quantitative character of the work. Although he had no source of monochromatic light except a ruby glass which gave a red light of average wave-length about 6530, Biot made a quantitative study of the influence of wave-length and of other physical conditions on rotatory power, expressing his results, whenever this was possible, by means of mathematical equations and diagrams.

Two of Biot's diagrams retain their interest even at the present time. The first shows, by means of a series of straight lines, the influence of dilution with water on the rotatory power of tartaric acid. This diagram enabled Biot to predict that dextro-tartaric acid when in the anhydrous glassy form would actually become lævorotatory at the red end of the spectrum at all temperatures below 23° C., a bold prediction that was verified experimentally ten years later.

The second of these diagrams was used by Biot to illustrate his discovery that the rotation of the plane of polarisation of light in quartz was inversely proportional to the square of the wave-lengths, using the figures determined by Newton for corresponding regions of the spectrum. In this diagram the thickness of quartz required to produce a given rotation was plotted against the square of the wave-length, and the result was a series of straight lines. Biot recognised that some of the readings differed from the calculated rotations by 2 or 3 per cent., but he was not in a position to decide whether these deviations were due to experimental errors or to some inaccuracy in his formula. Our own measurements have shown that Biot's diagram represents almost exactly the rotatory dispersion in quartz if the lines are drawn through a point a little to the right of the origin, and there can be little doubt that if more accurate methods of measurements had been available Biot's line of thought and method of representation would have led him almost inevitably to the simple formula for rotatory dispersion which has come into general use in recent years after the lapse of nearly a century.

2.—*Simple Rotatory Dispersion.*

As the accuracy of polarimetric work increased, the deviations from Biot's law of inverse squares became too important to be overlooked. The result was unfortunate, since those who destroyed the original formula had not got the skill to replace it by one that was more exact. For half a century, therefore, work on rotatory dispersion was limited to the occasional plotting of a curve of unknown form to represent the relationship between rotatory power and wave-length. As a natural result interest in the study of rotatory dispersion diminished, and (following the discovery of the Bunsen burner in 1866) the D line of the sodium flame acquired almost a monopoly as a source of light for the investigation of optical rotatory power.

During this period corrected formulæ were put forward by Boltzmann, who wrote $\alpha = A/\lambda^2 + B/\lambda^4$, and by Stefan, who wrote $\alpha = A + B/\lambda^2$; but these proved to be of little value, since they could not readily be made to fit the curves, and, being obviously empirical in character, could be used only as a means of interpolation between the experimental values.

This period of retrogression came to an end with Drude's application to optics of the electronic theory at the close of the nineteenth century. His theoretical investigations led to the enunciation of a somewhat elaborate formula for optical rotatory dispersion which (when approximate results only were required) could be used in the simplified form shown in the equation,

$$\alpha = \Sigma \frac{k_n}{\lambda^2 - \lambda_n^2},$$

where the dispersion-constants $\lambda_1^2, \lambda_2^2 \ldots \lambda_n^2$, could be deduced from the refractive power of the medium, while k_n represented a series of arbitrary constants depending on the rotatory power of the medium. A similar formula, which actually included the refractive index, was put forward to express the influence of wave-length on magnetic rotatory power. Drude tested his formula for optical rotatory dispersion in the case of quartz, whilst that for magnetic rotatory dispersion was tested in the case of carbon disulphide and of creosote; but for some years both formulæ remained almost barren so far as practical applications to measurements of rotatory dispersion were concerned. In particular, it may be noted (i) that a complete knowledge of the curve of refractive dispersion was required before either formula could be applied to measurements of rotatory dispersion, and (ii) that even the approximate formula for optical rotatory dispersion contained an indefinite number of arbitrary

[1] Abridged from the Bakerian Lecture delivered before the Royal Society on June 2, 1921.

constants. Drude himself did not apply his formula to a single member of the vast array of optically active liquids and solutions, which have been prepared and studied more especially from the time of Pasteur onwards, and he can, perhaps, scarcely be blamed for this omission, in view of the fact that the rotatory power of the great majority of these media had been determined for one wave-length only. It was therefore not until the problem of rotatory dispersion had been taken up afresh and new series of exact measurements had been accumulated that the unique merit of Drude's formula was established.

The results of these new tests were most striking. Fifty series of measurements of magnetic and optical rotatory dispersion were made and classified into groups with similar rotatory dispersion, in order to minimise individual errors of observation. It was then found (Lowry and Dickson, Trans. Chem. Soc., vol. 103, p. 1067, 1913) that the whole of these readings could be expressed within the limits of experimental error by using a single term of Drude's equation, involving only two arbitrary constants—namely, a "rotation-constant," k, and a "dispersion-constant," λ_0^2, as set out in the equation $\alpha = k/(\lambda^2 - \lambda_0^2)$.

The substances examined at this stage were nearly all compounds of simple structure—*e.g.* secondary alcohols of the aliphatic series; but the two methyl glucosides, each containing five asymmetric carbon atoms, were proved to obey the same simple law (Lowry and Abram, Trans. Faraday Soc., vol. 10, p. 112, 1914). A somewhat dramatic vindication of Drude's formula, in the case of compounds of much greater complexity, has, however, been provided by the more recent work of Prof. Rupe, of Basel, who published in 1915 (Ann. der Chem., vol. 409, p. 327, 1915) a series of measurements of the rotatory power for four different wave-lengths of some forty compounds of the terpene series. In order to determine the mathematical form of the dispersion-curves he plotted α against λ, log α against λ, log α against $1/\lambda$, α against $1/\lambda$, α against $1/\lambda^2$ (to test Biot's equation and Stefan's equation), and $\alpha\lambda^2$ against $1/\lambda^2$ (to test Boltzmann's equation); but in no case was there any indication of a linear relationship. The results obtained by plotting $1/\alpha$ against λ^2, in order to test the validity of the one-term Drude equation (Lowry and Abram, Trans. Chem. Soc., vol. 115, p. 300, 1919), are, however, most remarkable, since thirty-seven of the forty substances studied by Rupe give straight lines, and only three show any marked curvature. It is, moreover, noteworthy that two of these exceptional compounds agree in containing the group, $C:C(C_6H_5)_2$, although it is not clear why this group should be associated with the occurrence of abnormal optical properties.

Further work by Pickard and others has confirmed the fact that the rotatory dispersion of a vast range of organic compounds can be represented by the simple formula $\alpha = k/(\lambda^2 - \lambda_0^2)$, and that a satisfactory classification of optically active compounds can be made by distinguishing between "simple rotatory dispersion," where this law holds good within the limits of experimental error, and "complex rotatory dispersion," where marked deviations from the law are found.

3.—*Complex and Anomalous Rotatory Dispersion.*

Amongst the substances which do not obey the simple law of rotatory dispersion, tartaric acid and its derivatives have been conspicuous ever since Biot in 1837 directed attention to the peculiar behaviour of the acid in aqueous and in alcoholic solutions. The principal anomaly noted by Biot was the fact that the rotation, instead of increasing continuously with decreasing wave-length, rose to a maximum in the green, and then diminished again in the blue, indigo, and violet to values almost as low as those observed in the red region of the spectrum; but the extreme sensitiveness of the rotatory power of the acid to changes of temperature and concentration, as well as to the influence of solvents and of chemical agents, was in Biot's opinion at least as important an anomaly as the maximum in the curve of rotatory dispersion.

When, however, the quantitative basis for the study of rotatory dispersion had been destroyed, attention was no longer directed to the deviations from the law of inverse squares (which were then recognised as being universal), but to the qualitative peculiarities of the curves, which alone were regarded as justifying the use of the term "anomalous dispersion." The principal anomaly thus selected for special attention was the occurrence of a maximum; but a reversal of sign or a decrease of optical rotation with diminishing wave-length were sometimes included as anomalies of similar importance. The undue emphasis thus laid upon the qualitative anomalies has had some curious results; in particular, Winther not only adopted the view that the maximum is the sole criterion of anomalous rotatory dispersion, but actually insisted that this maximum must lie within the visible region of the spectrum. He therefore speaks of a dispersion-curve which "becomes normal in that the maximum passes into the ultra-violet," whilst a curve which cuts right across the axis is described as "normal with a maximum in the infra-red." A definition of anomalous dispersion which thus depends on the physiological properties of the eye, instead of on the physical properties of the medium, can scarcely be regarded as worthy of serious consideration, but it provides a suitable anticlimax to direct attention to the value of the more precise methods of treatment which prevailed when rotatory dispersion was first studied almost a century before.

A complete solution of the problem of anomalous rotatory dispersion has been found by returning to the mathematical methods of Biot and applying similar processes of analysis to curves plotted with the greater accuracy which modern physical apparatus has rendered possible. A series of dispersion-curves (Fig. 1) for aqueous solutions of tartaric acid of different concentrations will illustrate the typical forms of the curves that are encountered in studying the substances of this group.

These curves show clearly three principal anomalies—*inflexion*, *maximum*, and *reversal of sign*—appearing at various points on the experimental curves as the concentration of the solutions is altered.

Similar curves, but covering a wider range, are obtained when the esters of tartaric acid—*e.g.* methyl tartrate and ethyl tartrate (Fig. 2)—are examined as

homogeneous liquids at different temperatures or in a series of different solvents (Lowry and Dickson, Trans. Chem. Soc., vol. 107, p. 1183, 1915; Lowry and Abram, *ibid.*, p. 1193).

Careful mathematical analysis has shown that all

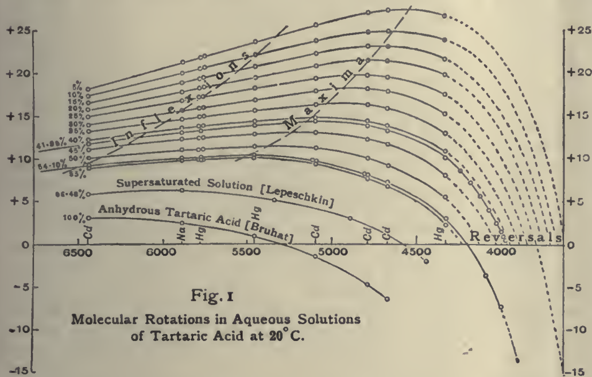

Fig. 1

Molecular Rotations in Aqueous Solutions of Tartaric Acid at 20° C.

these curves can be expressed by two terms of Drude's equation, of opposite sign and with unequal dispersion-constants—*e.g.*

$$\alpha = \frac{k_1}{\lambda^2 - \lambda_1^2} - \frac{k_2}{\lambda^2 - \lambda_2^2}.$$

The agreement is particularly good in the case of the esters. In the case of aqueous solutions of tartaric acid the ionisation of the acid appears to introduce an additional factor of complexity giving rise to small but systematic deviations from the values calculated by means of a two-term formula.

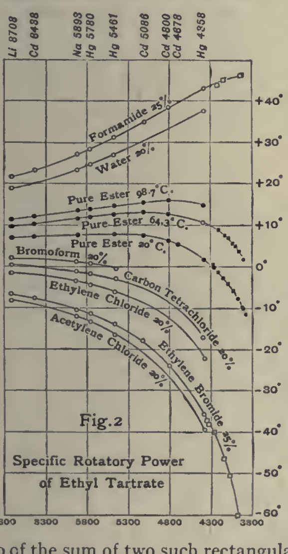

Fig. 2

Specific Rotatory Power of Ethyl Tartrate

In cases of "simple" rotatory dispersion Drude's formula postulates a linear relation between $1/\alpha$ and λ^2, but gives a rectangular hyperbola when α is plotted against λ^2. The corresponding dispersion-curves for methyl and ethyl tartrates are made up of the sum of two such rectangular hyperbolas, lying on opposite sides of a common horizontal asymptote, but working up to two different vertical asymptotes. These simple hyperbolas lie beyond the curves for solutions in formamide and in acetylene chloride, which are the highest and lowest of the series shown in Fig. 2, but every curve in this figure can be represented as a weighted mean of two such hyperbolas.

It should be noted that in this series of compounds the negative term always has a higher dispersion-constant than the positive term, so that the asymptote of the negative hyperbola is nearer to the visible region of the spectrum than that of the positive hyperbola. All the positive rotations are therefore drawn over towards the negative side as the wave-length diminishes, as in the top curve of Fig. 2, which shows a reversal of curvature on the extreme right. The curves in the upper part of Fig. 2 must therefore show, not merely one, but *all* of the features which are usually regarded as characteristic of anomalous rotatory dispersion—namely, (i) an inflexion, (ii) a maximum, (iii) a diminution of rotatory power with decreasing wave-length, (iv) a reversal of sign.

On the other hand, the curves at the bottom of Fig. 2 are negative throughout, since the positive term is always smaller than the negative term of the equation. There is therefore no inflexion, maximum, or reversal of sign. The curves obtained by plotting α against λ^2 are, however, not rectangular hyperbolas, but the weighted means of two hyperbolas, and require two terms of the Drude formula to represent them. Although, therefore, these curves are not anomalous, they are not "simple," and must be classed with the anomalous curves as "complex."

It should be noted that a small alteration in the numerical values of the constants of the equation for a complex curve may suffice to introduce the whole range of anomalies, or alternatively to remove them, whereas, to render a complex curve simple, one of the two terms in the complex equation must be made to disappear altogether. The difference between simple and complex dispersion is therefore probably of more significance than that between normal and anomalous dispersion, in spite of the more picturesque character of the latter contrast.

4.—*The Origin of Anomalous Rotatory Dispersion.*

It has been shown above that the curves of rotatory dispersion of organic compounds may be of three types—(i) simple, as in the case of the vast majority of the alcohols, acids, sugars, terpenes, etc., to which reference has already been made; (ii) complex, but without anomalies, as in the case of the tartaric esters when dissolved in solvents such as acetylene tetrachloride; (iii) anomalous, as in the case of tartaric acid and its esters. What, then, is the origin of the complexities seen in classes (ii) and (iii)? Mathematically they depend on the same fundamental factor—namely, the introduction into the equation of rotatory dispersion of a second term of opposite sign, which is absent in class (i). From the chemical point of view it is difficult to avoid the conclusion that the complexities expressed by the two-term formula are due to the presence in these liquids of two kinds of optically active molecules, differing in sign and in dispersive power, but each characterised by a simple rotatory dispersion corresponding with one term of the equation.

This suggestion is far from new. Biot himself, as long ago as 1836, produced an artificial anomaly when he attempted to compensate the optical rotatory power of lævorotatory turpentine by means of a column of dextrorotatory oil of lemon. Similar results were obtained with artificial mixtures of turpentine and camphor; and so long ago as 1858 Arndtsen, after establishing by his own measurements the unequal dispersive power of optically active compounds, made the following suggestions :—

"If one should imagine two active substances which do not act chemically upon one another, of which one turns the plane of polarisation to the right, the other to the left, and, in addition, that the rotation of the first increases (with the refrangibility of the light) more rapidly than that of the other, it is clear that, on mixing these substances in certain proportions, one would have combinations which would show optical phenomena precisely similar to those of tartaric acid, as M. Biot has already proved by his researches on different mixtures of turpentine and natural camphor. One could then regard tartaric acid as a mixture of two substances differing only in their optical properties, of which one would have a negative, and the other a positive, rotatory power, and of which the rotations would vary in different proportions with the refrangibility of the light."

This suggestion, made more than sixty years ago, can now be supported by two additional lines of argument: (i) the mathematical evidence that the rotatory dispersion of these substances is in fact the sum of two simple rotations—*e.g.* as expressed graphically by the fact that the complex curves obtained by plotting α against λ^2 are merely the weighted mean of two rectangular hyperbolas; (ii) the chemical evidence that mixtures of isomers do in fact exist, which fulfil the conditions laid down by Arndtsen. Of these optically active "dynamic isomerides" nitrocamphor was one of the earliest examples to be studied, and it is still one of the best illustrations that can be given of this group of phenomena.

The existence of two forms of nitrocamphor was proved by the discovery of mutarotation—*i.e.* change of rotatory power with time in freshly prepared solutions of the compound; but a mere trace of a catalyst, such as piperidine at a concentration of M/10,000, is sufficient to speed up the isomeric change to such an extent that mutarotation can no longer be detected. In tartaric acid and its esters similar conditions of rapid interconversion appear to prevail, since careful observations have failed to detect any lag of rotatory power after dissolution, dilution, distillation, or fusion. As in the case of nitrocamphor, however, it is possible to recognise, in addition to the usual mixtures, a certain number of derivatives of a fixed or homogeneous character, and these are characterised by opposite rotatory powers and unequal simple dispersions, precisely as we have postulated for the two modifications of the parent acid. Thus (i) tartar emetic differs from the other tartrates not only in showing a much higher rotatory power, but also in giving a dispersion-curve of the "simple" type which is characteristic of the vast majority of optically active organic compounds; (ii) on adding an excess of alkali to tartar emetic a lævorotatory derivative is produced, but this also exhibits simple rotatory dispersion; (iii) boric acid also possesses the power of fixing tartaric acid in a dextrorotatory form with simple rotatory dispersion.

In view of these observations it is difficult to resist the conclusion that tartaric acid, like nitrocamphor, can exist in two forms and yield two types of derivatives, and that the presence of these two types is responsible for the complex rotatory dispersion of the acid and of so many of its derivatives. The molecular structure of these two types is a fascinating problem which still awaits investigation.

Obituary.

Dr. G. B. Mathews, F.R.S.

Briefly recorded in Nature a fortnight ago, the death of Dr. George Ballard Mathews occurred in a Liverpool nursing home on March 19.

Born in London (February 23, 1861), of a Herefordshire family, Mathews' versatile intellect showed itself during his schoolboy days at Ludlow Grammar School, where the then head master instructed his boys in Hebrew and Sanscrit as well as in Greek and Latin. After a year at University College, London, where he studied geometry under Henrici, and of which body he later became a fellow, he entered St. John's College, Cambridge, which offered him the senior scholarship of his year either in mathematics or classics. Carrying out his intention of reading for the Mathematical Tripos he became a private pupil of Mr. W. H. Besant of St. John's. The keen competition for leading places in the Tripos of this period had brought fame to Mr. E. J. Routh as a coach and all the abler candidates went to Routh as a matter of course, for Routh had a long series of senior wranglers to his credit. However, Mathews' name was read out first in the list of 1883, this being the only break in a succession of about thirty consecutive seniors trained by Routh.

In 1884 Mathews was appointed to the chair of mathematics in the then newly-constituted University College of North Wales at Bangor, his election to a fellowship at St. John's taking place the same year. His colleagues at Bangor were all of the same generation as himself and included such men as Professors Andrew Gray, James Dobbie, and the late Henry Jones under the leadership of Principal Harry Reichel (the last three named have all since been knighted). The Bangor chair was resigned in 1896, and shortly followed by Mathews' election into the Royal Society and by his return to Cambridge as University Lecturer in Mathematics. During this period he was mathematical secretary of the Cambridge Philosophical Society for a time and also served on the Council of the Royal Society and on that of the London Mathematical Society. Resigning the Cambridge appointment in 1906 he returned to Bangor and, since 1911, held a special lectureship in the North Wales University College. The honorary degree of LL.D. was conferred by Glasgow University in 1915, and he again acted as professor of mathematics in Bangor during the two College sessions 1917–19. Dr. Mathews himself attributed the distressing series of illnesses which clouded

the last three years of his life, and ended it, to the enforced system of rationing during the latter part of the war.

While thoroughly familiar with all branches of pure mathematics, Mathews' main interests were in the theory of numbers and projective geometry. The theory of numbers which, in its widest sense, is the theory of discrete as opposed to continuous magnitude, has passed through four well-defined stages of development. First there came the Diophantine analysis proper, of which the greatest exponents, after Diophantos among the ancient Greeks, were Fermat and Euler. In this the general problem is to determine all the solutions in rational numbers of a system of m $(\angle n)$ algebraic equations.

$$R_i(x_1, x_2, \ldots x_n)=0, \quad i=1, 2, \ldots m.$$

Next came the discovery of the law of quadratic reciprocity which rendered possible a discussion of quadratic arithmetical forms, so ably expounded by Gauss in the "Disquisitiones Arithmeticæ." Such writers as Lejeune-Dirichlet, Eisenstein, and Stephen Smith added much to what Gauss had done, and a scholarly introduction to the whole theory was given by Mathews in his "Theory of Numbers" of 1892. A problem which arises in the theory of quadratic forms (the determination of the class-number) was the forerunner of the analytical theory which is intimately bound up with certain transcendental functions of a complex variable. It had little attraction for Mathews (though his book contains an introduction to it), but has recently received much attention from Prof. E. Landau, Prof. G. H. Hardy, and the late S. Ramanujan. The fourth stage was marked by Dedekind's discovery of his theory of ideal numbers, which restore completely to a system of algebraic numbers certain factorisation properties of ordinary integers that appear at first to be lost. Taking numbers of the type $a+b\sqrt{-5}$, where a, b are ordinary integers, a threefold factorisation of 21 is possible, viz.:

$$21=3\times 7=(4+\sqrt{-5})(4-\sqrt{-5})$$
$$=(1+2\sqrt{-5})(1-2\sqrt{-5}),$$

whereas none of the factors $3, 4+\sqrt{-5}$, etc., is decomposable into two factors $(a+b\sqrt{-5})(c+d\sqrt{-5})$.

Mathews' was probably the first mind in England to realise the far-reaching effect of Dedekind's discovery, two papers by him on the subject appearing in the London Mathematical Society's Proceedings of 1892. The tract "Algebraic Equations" on a kindred topic, written fifteen years later, contains a masterly exposition of Galois' theory, completed by Jordan and others, showing how the different types of irrationality which can be defined by an algebraic equation are associated with different types of group.

Written in collaboration with Prof. Andrew Gray, the "Treatise on Bessel Functions," concerned mainly with physical applications, is still a standard work. The "Projective Geometry" (1914), inspired by Henrici's lectures in London many years before, contains two unusual features: first, an exposition of the logical groundwork of the subject, and secondly, an account of Staudt's theory of complex elements (whereby a real involution defines a complex point or line). He also brought out a new edition of R. F. Scott's "Determinants" (1904), and contributed articles on *Number* and *Universal Algebra* to the 1910 edition of the "Encyclopædia Britannica."

Most of Mathews' mathematical papers appeared in the London Mathematical Society's Proceedings or in the "Messenger of Mathematics." A few of them are geometrical, and nearly all the rest have an arithmetical bearing. Pride of place, perhaps, should be given to a four-page note of 1897, in which he explained a method of reducing multiple partitions to a single partition. Several papers were written on the complex multiplication of elliptic functions, a subject which had a singular fascination for Mathews. The publication of a manuscript on the lemniscate functions has been delayed by the war and his subsequent illness.

Ever since the mid-eighties NATURE has published frequent reviews and articles from Mathews' pen. These articles, most of which appeared over the initials "G. B. M.," were always written in a careful and scholarly style; they contained his considered opinion on the book or point concerned. In conversation with the present writer he once expressed the opinion that some of his best work had appeared in NATURE reviews.

A man of simple tastes and naturally retiring by disposition, Mathews expressed sound judgment on both men and affairs. Some of his views, perhaps, were those of an idealist, and hardly feasible in the domain of practical politics. His capacity for maturely grasping everything with which his mind came into contact made him unique in the experience of his friends. Only one or two sides of so versatile a man's brilliant intellect really appealed to most people. When he was appointed professor of mathematics at Bangor, at the age of twenty-three, it was manifest that he could equally well fill four or more chairs in the college. During recent years he spent much time in reading and translating Arabic: he was also a competent musician.

W. E. H. B.

DR. J. T. MERZ.

DR. JOHN THEODORE MERZ, whose death on March 21, in his eighty-second year, was announced last week, was a son of Dr. Philip Merz, headmaster of the Chorlton High School, one of the pioneer institutions of higher education in Manchester. He was an acknowledged authority upon industrial chemistry and took a leading part in the industrial development of electricity supply, being one of the founders of the Newcastle-upon-Tyne Electric Supply Company. By the use of his great scientific and practical knowledge, he rendered invaluable service to the industrial community of Tyneside and the counties of Northumberland and Durham.

Dr. Merz will, however, be most widely remembered on account of literary activities, which go so far back as 1864, when he wrote a paper, which was published in Germany, on Francis Bacon, and another on Kant. For a long time the work by which he was best known was a small but much appreciated volume on Leibniz, contributed in 1884 to Blackwood's "Philosophical Classics for English Readers." A German translation of this appeared in 1886. These publications, however, were mere preliminaries to that which he had planned as the great work of his life, "The History of European Thought in the Nineteenth Century." The first volume of this was published in 1896, the fourth and last at the end of 1914. From the first

the wide-ranging history, learned but never dry, was a literary success, receiving praise from all sides and from thinkers of all schools. The impartiality with which the author treated the contributions made to thought by England, France, and Germany respectively was universally recognised. This work he was able to complete so far as scientific and philosophical thought are concerned. A third part to be devoted to the less systematic thought that has found its expression in *belles lettres* was projected, and was to consist, like the two parts on scientific and philosophical thought, of two volumes; but this Dr. Merz finally decided, though he had collected much material, must be left for some successor.

Dr. Merz's labours, however, did not by any means cease. At the end of 1915 he published a very interesting essay on Religion and Science, in which he showed that the certainty of science within its limits depends on its method of abstraction. A view of things "all together," in which the mind, without which the external world cannot be known, is restored as part of the total system of reality, leads to recognition of the religious attitude as a mode of comprehending the universe, including man. Philosophy mediates between science and religion, explaining the validity in its own manner of each mode of viewing things.

In a like essay, "Fragment on the Human Mind" (1919), Dr. Merz showed his freedom from some prejudices of that reaction in nineteenth-century English thought which had gone to Germany for a more spiritual doctrine than the native philosophy seemed to result in. Knowing and appreciating the rule of Kant and Hegel and their successors, in the end he found in the psychological method of Locke, Berkeley, and Hume the most valid, as well as the most accessible way to show the fallacies of the "mechanical Philosophy" when regarded, not simply as the most powerful instrument of scientific thought, but as revealing the ultimate nature of the universe. To give us a suggestion that reality is spiritual, Locke's "plain historical way," namely, the method of introspection, remains sufficient.

COLONEL SIR HENRY THUILLIER, K.C.I.E.

THE late Sir Henry Thuillier, who died on March 4, was Surveyor-General of India from 1886 to 1895, and was distinguished as an able and tactful administrator. His name is so generally associated with administrative work, that his success as a geodetic observer in the earlier part of his career is apt to be overlooked.

Thuillier was commissioned in the Bengal Engineers in 1857, the year of the Mutiny, and he was appointed to the Great Trigonometrical Survey of India in 1859. In 1859–1861 he was one of the observers employed in carrying a chain of principal triangulation round the Punjab frontier along the line of the river Indus; this chain has been the fundamental base of all the later surveys, which have been extended during campaigns into Afghanistan, Waziristan, and Tirah.

In 1862 Thuillier was appointed to the eastern frontier of India, and for the next six years he had the difficult task of extending the principal triangulation eastwards from Calcutta to Burma. During the first half of the nineteenth century the geodetic triangulation had been carried across mountains and plains, deserts, fields and forests, and the observers had had to adapt their methods of observation to the varying types of country; but in Eastern Bengal Thuillier encountered a type of country that had not been met with before, and which was probably the most unsuitable of all types for triangulation. He had to carry chains of triangles over the deltaic swamps of the Ganges and Brahmaputra; the country was absolutely flat and overgrown with heavy jungle.

Thuillier had to cut glades through the jungle so as to render the several stations of his triangulation mutually visible from one another. The party suffered continually from malaria; the clearing of the glades was so laborious that their width had to be limited to a few feet. The exact line in which any particular glade had to be cut from one station to another was not known with sufficient accuracy to enable the men to clear the jungle in the correct direction, and numerous trial glades had to be cut in order to determine the true alignment. In one year on the Brahmaputra series of triangulation, Thuillier had to clear 700 miles of glade through dense jungle, and in the six years the total length of the clearance lines was nearly 4000 miles.

Sir Henry Thuillier had also considerable experience of surveying at high altitudes. He was trained in the famous Kashmir survey of Montgomerie and Godwin-Austen (1861), and from 1870 to 1873 he was in charge of the survey of the Kumaun Himalayas, including the glacial areas of Nanda Devi and Trisul. Many of his survey marks were above 20,000 feet.

PROF. J. A. GREEN.

WE are grieved to hear of the sudden death, following upon an operation, of Prof. John Alfred Green, professor of education in Sheffield University. Many of us knew Prof. Green best in connection with the Educational Science Section of the British Association, of which he was for several years Recorder. He had the virtue we admire in a Tangye silent gas engine—converting all his energy into work and none into fuss—of a restrained enthusiasm, able to work in harness, but no less enthusiastic because he did not boil over into the vapid. Hence he was invaluable in the early days of the Educational Science Section, when many doubted whether there were, or could be, such a thing as educational science. But Prof. Green had visions and lived to realise them. He was secretary of the Committee on Mental and Physical Factors involved in Education, and the opening pages of the Report presented at Sheffield in 1910 make his attitude clear: "application of experimental methods to the investigation of mental phenomena" . . . "study of the persons to be educated and their attitude towards methods of instruction." If Section L still devotes a day annually to education and psychology, that is largely Prof. Green's doing. The work was carried further by him in *The Journal of Experimental Pedagogy*, which he edited. In that journal Prof. Green has left us a monument and a guidepost which may encourage us to go forward in the way which he was one of the first to tread.

H. R.

Current Topics and Events.

The Board of Trade announces that, in connection with the Safeguarding of Industries Act, judgment has been given by the referee in arbitrations regarding the following articles. Against the name of the article is shown the decision of the referee, *i.e.* whether it has been properly or improperly included in, or excluded from, the lists of articles chargeable with duty under Part I. of the Act:

Article.	*Judgment.*
Calcium Carbide . . .	Properly excluded.
R. Lactose	Improperly included.
Cream of Tartar, Tartaric Acid, Citric Acid	Improperly included.
Planimeters and Integrators (Planimeter type) . . .	Properly included.
Calculating Cylinders . .	Properly included.
Mucic Acid	Properly included.

In two cases, viz. that of R. lactose and that of cream of tartar, tartaric acid, and citric acid, the decisions are against the Board of Trade, and those substances are accordingly withdrawn from the lists of dutiable articles as from March 25, which is the date of signature of the awards. The *Chemical Age* of March 25 announces that an inquiry which should have opened into a complaint that barium peroxide had been wrongly included in the list had been decided by agreement between the producers and consumers. It is quite clear from these results that sufficient care had not been exercised by the persons concerned in drawing up the list in the first case, and if the announcement in the *Observer* of March 26, to the effect that the Board of Trade were to recommend the repeal of the Act, is correct, it would appear that the difficulties of working such a measure had become too great to justify its further continuance.

An exceptionally severe frost was experienced in most parts of England in the early morning of April 2, and the minimum temperatures reported to the Meteorological Office were in many places unprecedented for April. The temperature in the screen at Kew Observatory was 26°, which is the lowest April reading since observations commenced more than half a century ago. At South Farnborough, Hants, and at Benson, Oxon, the sheltered thermometer registered 21°. In consequence of the clear sky which prevailed the exposed thermometer fell generally about 10° below that in the screen, and at Shoeburyness the reading on the ground was 11°. At Greenwich Observatory the sheltered thermometer registered 25° and the terrestrial radiation temperature was 15°. The records at Greenwich, extending back to 1841, show only one instance of a lower temperature in the screen in April, the thermometer registering 23° on April 17 in 1847. There was a reading of 25° on April 1, 1859. Very heavy snowstorms were experienced in the south-western districts during the night of March 31 and on the following day, the ground being covered to a great depth. The storm was due to a disturbance moving from Cornwall across the English Channel. This storm area was followed by a region of fairly high barometric pressure which accompanied the cold snap.

The Council of the Optical Society is arranging a programme of papers dealing with motor head lights, having reference more particularly to the optical problems involved. The question of "glare" or "dazzle," and the methods proposed for overcoming it will be considered alike from the point of view of the optician, the lamp manufacturer, and the road user. The meeting will be held at the Imperial College of Science and Technology, South Kensington, on May 11, and any one desiring to contribute to the discussion, to exhibit models, or to give experimental demonstrations is requested to communicate with the honorary secretary of the Society, Mr. F. F. S. Bryson, Glass Research Association, 50 Bedford Square, W.C.1.

The *Times* announces that the Mount Everest expedition was to leave Darjeeling on March 26 for Tibet. Brig.-Gen. C. G. Bruce, chief of the expedition, was accompanied by Col. E. L. Strutt; Mr. G. L. Mallory, of last year's expedition; Dr. T. G. Longstaff; Maj. E. F. Norton; Dr. A. M. Wakefield; Mr. T. H. Somervell: Capt. J. Noel; Capt. G. Bruce; and Capt. E. J. Morris. Capt. G. Finch and Mr. C. G. Crawford remained behind to superintend the transport of the oxygen outfit upon which a great part of the success of the expedition depends. It will be noticed that the party is considerably larger than the one that made the successful reconnaissance last year. No trouble seems to have been experienced in enlisting porters among the hillmen. It is hoped that by April 6 the whole expedition will have assembled at Phari Dzong ready to set out and establish advanced bases in the Rongbuk and East Rongbuk valleys. A considerable time will be spent in training the porters in the use of ropes and ice axes and, in consequence, no delay is anticipated from the fact that the oxygen apparatus has not yet reached India.

For the purpose of carrying on the Ice Patrol Service provided for by the International Convention for the Safety of Life at Sea, the U.S. cutter *Seneca* has been detailed for duty off the Newfoundland Banks. According to the North Atlantic Meteorological Chart for April, this vessel was to go to sea in February 6 with orders to locate icefields and keep in touch with the drift of icebergs. About April 1, when the ice has moved well south, the U.S. cutters *Tampa* and *Modoc* will join the patrol, the three vessels continuing their work throughout the season of dangerous ice conditions. On getting in touch with the ice, the *Seneca* will report to the Hydrographic Office, New York, either direct or through any vessel within reach. Daily wireless messages will advise ships at sea. All messages will be sent in plain English. Masters of trans-Atlantic vessels are asked to report to the patrol vessels the location of icebergs or drift-ice and the temperature of the water every four hours between latitudes 39° N. and 48° N. and between longitudes 53° W. and 44° W. These data are required in order to ascertain the branches of the Labrador current.

A DEPARTMENTAL COMMITTEE has been appointed by the Minister of Agriculture and Fisheries "to inquire into the origin and circumstances of the recent outbreak of foot-and-mouth disease and into the policy and procedure which was pursued in dealing with the disease, and to report whether any alteration of the methods of administrative control hitherto adopted, or any amendment of the existing law, is necessary or desirable." The committee is constituted as follows: Capt. E. G. Pretyman (chairman), Mr. A. Batchelor, Mr. David Ferrie, Mr. F. W. Garnett, Mr. H. German, Mr. William Graham, Mr. Alfred Mansell, Sir G. Douglas Newton, Prof. J. Penberthy, and Mr. W. R. Smith. The secretary of the committee is Mr. S. A. Piggott, Ministry of Agriculture and Fisheries, 4 Whitehall Place, S.W.1, to whom all communications should be addressed.

THE British Rainfall Organization has removed its quarters from Camden Square, where its work has been carried on for more than half a century, to the Meteorological Office at South Kensington. For about three years the organization, which was formerly of a private nature, has been carried on as part of the official meteorological service of the country. It is thought that the general meteorological work will be greatly facilitated by being under the one roof in Exhibition Road, South Kensington. The Rainfall Organization was transferred from March 20. The absorption of the Meteorological Office in the Air Ministry has made it necessary for parts of the Office to be at the Air Ministry Offices in Kingsway. The office at South Kensington deals with climatology and instruments.

MR. ROBERT SARGEANT has retired from the Meteorological Office after rather more than 50 years' service. He entered the office in 1871 when it was controlled by a Committee of the Royal Society, at a time when ordinary weather forecasts, initiated by Admiral Fitzroy, had been discontinued. At that time weather reports were both received and published; they were used for the issue of storm warnings. Throughout the whole period of his service, Mr. Sargeant was engaged in the Daily Weather Report and Forecast Branch. He was also an Inspector of Meteorological Stations, and prior to his retirement had become Assistant Superintendent of the Forecast Branch. Mr. Sargeant's claim as a forecaster was based upon long experience and was chiefly associated with empirical rules; indeed, he is almost the last of a class which is being superseded by mathematicians and physicists who are working at the foundations of weather forecasting along strictly scientific lines.

THE number of journals entirely devoted to the study of earthquakes and volcanoes is small, and we welcome the publication of a new one, *Seismological Notes*, issued by the Imperial Earthquake Investigation Committee, Japan, and intended to contain preliminary reports on the Tokyo seismographical observations. To the first number Prof. Omori contributes two notes, one of which, on the great Chinese earthquake of December 16, 1920, contains reproductions of several Tokyo seismograms. He locates the origin in lat. 37° 5′ N., long. 106° 5′ E., a point close to several towns at which the shock was most disastrous, and between the centres of the great earthquakes of 1556 and 1561. The former of these earthquakes, by which more than 830,000 persons were killed, was probably the most disastrous of which we have any record.

THE third general meeting of the West Yorkshire Metallurgical Society, held in the City Museum, Leeds, on Saturday, April 1, took the form of a symposium of papers on the electric melting of metals; three original papers were read and discussed. The meeting was the last of a very successful winter session of this newly-formed metallurgical society. The membership, open to metallurgists, engineers, students, and others technically interested in the refining and working of metals, is steadily growing, and it is hoped that by next session the roll will contain a hundred members. The winter programme consists of meetings for the reading and discussion of papers in towns covered by the Society's activities, such as Leeds, Bradford, and Huddersfield. In addition to this and a summer programme comprising afternoon visits to works of interest to the members, the Society hopes to carry out suitably organised co-operative research through its members. The first president is Mr. T. E. Hull, and the hon. sec. is Mr. H. C. Dews, 17 St. John's Road, Huddersfield.

THE second annual report for 1921 of the Glass Research Association contains, in addition to the list of officers and members and its balance sheet, a statement of the problems already investigated and those under test. It appears that in addition to laboratories, now fully equipped, which the Association itself possesses at 50 Bedford Square, London, W.C.1, other institutions such as the National Physical Laboratory, the Department of Glass Technology, University of Sheffield, the British Refractories Research Association, and the Industrial Fatigue Research Board have all undertaken problems on behalf of the Association. Of the specific and definite results, one may refer to an investigation on the detection of cords in glass, the formation of "bloom" on lamp-blown glassware, the purification of mercury, the determination of the viscosity of a series of glasses over a limited range of (comparatively low) temperature, and the effect of the presence of chlorides and sulphates on the melting rate, working properties, and development of opalescence in lead glasses. On these subjects reports have appeared in the Bulletin of the Association. On the subject of glass-works practice, a new type of annealing lehr has been designed and erected, and a new furnace, an oil burner, and a cracking-off machine developed. References to other work and to research contemplated range over a wide field, but one of the subjects specially emphasised is that of glass refractory materials, and it is expected that co-operation with the British Refractories Research Association will carry forward investigations in this field speedily.

Messrs. A. Gallenkamp & Co., of Sun Street, E.C., have issued a catalogue of the latest forms of electrical resistance furnaces manufactured by them for various purposes. The heating element consists of a special alloy in the form of wire or strip, wound over a silica tube or muffle, and the furnaces are so constructed that the element may readily be removed by the user when burnt out, and replaced by a spare part. The maximum working temperature is 1000° C., and special types of furnace are made for the determination of carbon in steel, the estimation of ash in coal, the Lessing coking test for coal, and for organic combustions. The ordinary patterns are suited to such operations as the heat treatment of specimens of metals, the determination of the critical points of steel, and the checking of pyrometers against a standard. The power consumed by the furnaces when working at 1000° C. ranges from 400 watts for a tube 12 inches long and 1 inch diameter to 2300 watts for a muffle $14 \times 7 \times 4\frac{5}{8}$ inches. Details of accessories such as rheostats for controlling the temperature, ammeters, etc., are given, and the prices are also stated—a feature often absent from modern catalogues.

A number of reprints of communications made to the Edinburgh meeting of the British Association have been issued from the office of the Association in Burlington House, Piccadilly, W.1. We have received numbers 1-7 as follows: (1) Science and Ethics, by Dr. E. H. Griffiths, 9*d.*; (2) The Structure of Molecules, 9*d.*; (3) The Effects of the War on Credit, Currency, Finance, and Foreign Exchanges, 1*s.* 6*d.*; (4) Complex Stress Distributions in Engineering Materials, 3*s.* 6*d.*; (5) Charts and Pictures for Use in Schools, 1*s.*; (6) An International Auxiliary Language, 1*s.*; and (7) Report of the Conference of Delegates of Corresponding Societies, which contains Sir Richard Gregory's presidential address, "The Message of Science." It will be a great convenience to have these discussions and reports in pamphlet form, and it is to be hoped that the demand for these reprints will justify the Association in publishing similar reprints of contributions to future meetings.

Our Astronomical Column.

A Study of Obscure Nebulæ.—There have been many notes in recent years on regions of the sky where there is a deficit in the star-density as compared with neighbouring regions, the explanation generally assigned being an obscuring veil of dark nebulosity. We may refer in particular to one in Mon. Not. R.A.S. for November 1920 dealing with some barren regions in Taurus as shown on the Franklin Adams charts. Rev. J. G. Hagen, S.J., Director of the Vatican Observatory, has been examining these regions for the last ten years with the 16-inch refractor at the Observatory. He states that he can see these nebulosities, not as dark objects, but as faintly luminous ones. He discusses their distribution in *Scientia* for March; they are seen in all parts of the sky, but are densest towards the galactic poles, and diminish in extent and density as the galaxy is approached. He states that they are entirely absent in rich galactic star fields, and supposes that the nebulous material has been wholly transformed into stars in these regions. He places the obscure nebulæ outside the galaxy and asserts that their greater faintness in low galactic latitude is the result of greater distance; this does not appear to be sound, as the surface brightness of objects of sensible area is unaffected by distance provided that the intervening space is perfectly transparent. There is the further difficulty that in such barren fields as those in Taurus there is a deficiency not only of distant stars, but apparently also of nearer ones, suggesting a much smaller distance for the obscuring cloud. Thus while the visual study of these interesting regions is thoroughly useful work, there seems to be need of further examination of the significance of the results obtained.

Spectroscopic Study of Procyon's Orbit.—Dr. Lunt directs attention in *Astrophys. Journ.* for January to the aid that the spectroscope may render in the study of this system. The companion, discovered by Schaeberle in 1896, is a very difficult object and observations have been scarce of late. Dr. Lunt quotes the figures that he deduced from his measures on plates taken between 1909 and 1912. These appear to indicate a diminution in the approach of the principal star to the sun, which was 3·74 km./sec. in 1909 and 3·56 km./sec. in 1912; he points out that observations made now will be fairly decisive as to the pose of the orbit-plane, as there would be a difference of $1\frac{1}{2}$ km./sec. on the two assumptions. As one of the nodal passages is now at hand, the conditions are more favourable than they will be till 1938, when the other node is passed. He is himself arranging for a series of plates and asks for co-operation elsewhere. The approach of the centre of gravity towards the sun is given as 3·52 km./sec.; corrected for the sun's motion, the system is approaching with a speed of 19 km./sec. in a line inclined 14° to the line joining sun and star.

Recent Magnitudes of Novæ.—The appearance of a new star in the heavens at once attracts the attention of a large number of observers who follow very carefully the changes of magnitude and the variations in its spectrum. When, however, the magnitude has dwindled down to about 8 or 9, interest greatly diminishes; the star becomes too faint for spectroscopic analysis except with large telescopes, and the small and slow changes of magnitude are not watched by many observers. It is, however, very important to follow novæ so long as possible in order to keep in touch with the later variations. Great interest is, therefore, attached to the series of observations made by Dr. W. H. Steavenson of six novæ during the summer and autumn of 1921 (*Monthly Notices*, R.A.S., vol. 82, November 1921). Nova Ophiuchi (1848) gave evidence of variability in a period of about fifty days, the magnitudes varying from about 12 to 13. Nova Aquilæ (1918) is still slowly waning, the mean magnitude falling from 9·4 to 9·9, with a possible long-period variation. Nova Cygni (1920) is also still fading slowly, the mean magnitude during the period of observation falling from 9·4 to 10·0. Nova Cygni (1876), a star now very near the limit of visibility, exhibited practically a constant magnitude, namely, 14·81. The same is the case with Nova Lacertæ (1910), which has varied only 0·1 mag. from 14·1. On the other hand, Nova Persei (1901) has shown a marked variability of an irregular type, the two extremes of brightness being 12·27 and 13·36. The star was accompanied by a small patch of nebulosity about 5″ in diameter.

Research Items.

The Organism and Environment.—In an article on "The Organism and its Environment" (*Scientific Monthly*, March 1922), Dr. F. B. Sumner emphasises the difficulty of drawing any sharp line between these two categories. Citing as examples the nest of a bird, the tube of a caddis-worm, the shell of a mollusc or a tortoise, the varying fluids and gases which circulate in animals from sponges to fishes or seals, and the many metabolic changes of substances entering or leaving the body, he shows that the distinction between organism and environment must often be difficult or arbitrary. Some of his remarks have a direct bearing on the discussion of biological terminology which has taken place recently in this journal. Thus he says, "Every character has a hereditary basis" and is likewise due to "interaction . . . with the . . . environment." He goes on to say, "The familiar question, Which is the more important, heredity or environment? is not capable of answer when stated in that form"; he points out that the question should be framed on these lines: Are the *differences* between related organisms in any particular case due to *differences* in heredity or to *differences* in environment? When stated in this way it is seen that some characters or differences are primarily due to heredity and some to environment, and the quibble about all characters being equally acquired and equally inherited ceases to be of scientific value.

Studies on Arthropoda.—Dr. H. J. Hansen has issued, "at the expense of the Rask-Ørsted Fund," under the title "Studies on Arthropoda, I." (Copenhagen, 1921), three papers—one, illustrated with four plates, on a collection of Pedipalpi, etc., from West Africa, another on the post-embryonic occurrence of the median "dorsal organ" in Crustacea, malacostraca, and a third on stridulation in decapod Crustacea. In this last paper Dr. Hansen has brought together the records of the species of decapods in which stridulating organs are present, and gives an account of two further examples which he has discovered in a species of Ovalipes (one of the Portunidæ) and in Acanthocarpus (family Calappidæ). A stridulating organ consists usually of a regular row of small tubercles or a file-like series of ridges, *e.g.* on the carapace, which can be rubbed by a ridge, or a regular row of tubercles or ridges, or a sharp margin situated on some movable part of a neighbouring appendage. The sound produced by living crabs by means of the stridulating organ has been heard in the case of about half a dozen species. Dr. Hansen points out that a stridulating organ is developed in all species of Ocypoda except one, and in the Indo-Australian *Ocypoda ceratophthalma* one of the two series of ridges is composed of ridges of two sizes, coarse and very fine, so that the tone produced is deep or high, according as the coarse or fine ridges are rubbed. In discussing the use of the stridulating organ Dr. Hansen quotes Col. Alcock's view that this organ serves the crab to give warning to trespassers of its own species about to enter its burrow, but he suggests that some naturalist who has at his disposal living examples of Ocypoda should carry out investigations with the view of elucidating further the use of these organs.

Hygrometry.—The report of the discussion on hygrometry which was held by the Physical Society of London in November last has been issued with the Proceedings of the Society for February 15. It extends to 95 pages and is the most comprehensive publication on the subject which has appeared for many years. For some time one of the principal problems of hygrometry has been to develop a method which would determine, with an accuracy of 1 per cent., the fraction of saturation of air at temperatures below the freezing-point of water. The chemical method of absorbing the moisture is quite satisfactory at ordinary temperatures, but at temperatures below the freezing-point, the weight of moisture present is small and the method becomes difficult owing to the deposition of dew on the weighing tubes and other apparatus used. The dew-point method in its various forms is applicable at all temperatures and has been employed at the National Physical Laboratory as the standard of reference. The wet and dry bulb instrument fails at temperatures below the freezing-point, while the hair hygrometer continues to act although its indications are not always trustworthy. There appear to be some grounds for taking the decrease in length of the hair from its length when saturated as proportional to the logarithm of the relative humidity down to a relative humidity of 10 per cent.

Liquid Inclusions in Glass.—Some interesting experiments on the production of liquid inclusions in glass, made by Mr. Charles E. Benham, are described in the *Geological Magazine* for March. Although liquid inclusions in crystals of sodium chloride, alum, and other salts resemble in many respects those in quartz and exhibit Brownian movement of the more minute enclosed bubbles, there is reason to believe that their origin is not the same. Artificial inclusions approximating more closely to the cavities in minerals were prepared by boiling resin in water tinted with gamboge. Some of the cavities produced contained small quickly moving bubbles, and in others the gamboge particles were in rapid motion. In order to form similar artificial inclusions in glass approximating more nearly to those found naturally in quartz, a small glass tube about 3 inches long and a quarter inch external diameter was partially filled with water and sealed at both ends. It was enclosed within an unbaked brick and submitted to the usual process of firing in a brick kiln at a temperature of about 1200° C. After this treatment the glass was found to contain microscopic liquid inclusions with vapour bubbles comparable with those found in quartz. The experiment was repeated with similar results.

The Atomic Weight of Chlorine.—From the researches of Dr. F. W. Aston it is known that ordinary chlorine, atomic weight 35·46, is a mixture of two isotopes of atomic weights 35 and 37. The constancy of this ratio has been proved by the concordance between the determinations of the atomic weight made in different laboratories. This chlorine, without exception, came from minerals deposited by sea water. There is a possibility that the ratio might not be the same in chlorine arising from primary minerals not deposited from sea water, and this question has been taken up by Mlle. Ellen Gleditsch and B. Samdahl (*Comptes rendus*, March 13). They prepared salt from an apatite (calcium chlorofluophosphate) found in primary rocks, and after careful purification from fluorine, bromine, and iodine, found the atomic weight of the chlorine to be 35·49, 35·45, 35·46, the same as that of ordinary chlorine. Hence at the time of the formation of the minerals of the primary magma, the two chlorine isotopes were in the same ratio as at the present time.

The British Cotton Industry Research Institute.

THE new laboratories of the British Cotton Industry Research Association, at the Shirley Institute, Didsbury, Manchester, were formally opened by H.R.H. the Duke of York, K.G., on March 28. His Royal Highness was welcomed by the Chairman of the Council, Mr. Kenneth Lee, and the Director of Research, Dr. A. W. Crossley, in the presence of about 1500 guests, including representatives of most of the Universities. Mr. Kenneth Lee gave a brief review of the development of mechanical skill in the cotton trade, and explained how it was that the present leaders in the industry had become so convinced of the need for scientific inquiry on a large scale that, with the help and encouragement of the Department of Scientific and Industrial Research, they had established an Association for research on a co-operative basis. He spoke appreciatively of the help which University laboratories could contribute, and pleaded for their sympathetic co-operation, but he explained that the application of scientific methods and discoveries which were so much needed by the industry could be rendered most effectively by a group of scientific workers making their experiments in a special institution where they could obtain a closer knowledge of the processes involved than can be gained during an academic career.

His Royal Highness, in declaring the Institute open, congratulated the Association on securing the loyal support of the vast majority of the firms engaged in the industry and the various organisations of Labour, and emphasised the Imperial value of the close union which existed between the Research Association and the Empire Cotton-growing Corporation.

So far back as May 23, 1917, the opinion was expressed at one of the meetings of the provisional committee which organised the Cotton Industry Research Association that "the site of the Research Institute should not be less than five acres in extent; that it should be in pleasant surroundings, free from vibration due to traffic, and easily accessible both from the University (of Manchester) and from the centres of industry." These conditions are admirably fulfilled in the Shirley Institute, to which brief reference has already been made in Nature (1920, vol. cvi. pp. 411-413). The house and laboratories are nearly 250 yards from the main road, the grounds are bounded on the south by open fields, the prevailing winds leave the air free from the smoke clouds of both Manchester and Stockport, and the centre of the city can be reached in about half an hour.

The new laboratories have been designed to secure maximum adaptability, since it is almost impossible to predict which will be the predominant department in a few years' time. A "unit size" room has been created, and the separate laboratories are made in multiples of this unit. All the equipment is, so far as possible, uniform in design, and future extensions of the laboratories will be carried out on the same plan, so that the physics department, for example, could be moved to another portion of the building with the knowledge that all its furniture would fit into the new rooms.

Fig. 1.—The Shirley Institute for Cotton Research.

The ground plan of the new laboratories, representing two-fifths of the projected scheme, is given in Fig. 2. The completed portion is a one-storey building, divided into a central block 170 ft. × 54 ft., and an end block 83 ft. × 32 ft., the former being subdivided by the entrance hall and a long corridor into four departments each 22 ft. wide, which are partitioned off by breeze-block walls into one-, two-, or three-unit rooms as best adapted to the special requirements of the department. The outer walls, 21 in. thick, and the walls of the corridor bear the weight of the saw-tooth roof, which provides for north lighting. The span of each section of the roof is 10 ft. 6 in., and therefore the "unit room" is 22 ft. × 10 ft. 6 in.

All the supply lines, including 4-in. gas and water mains, hot-water, steam, and compressed air circuits, electric lighting and power cables, lead from the special battery of twenty two-volt "Exide" cells, and telephone wires are carried along a passage 5 ft. high under the central corridor. The branch lines for the different rooms of the central block are

brought under the floors, the secondary mains for gas and water being closed circuits with control valves at each end. The drainage pipes also pass first into the sub-floor, the height of which is 3 ft. 6 in., so that all vital supply and waste systems are accessible at any time. The laboratories are heated by radiators at the floor level, and hot-water pipes are also conveyed around the ceilings to prevent down-draughts from the glazed roof.

With the exception of the main chemical laboratory and balance-room, none of the rooms have fixed benches. In most cases the supply-lines and small sinks are held in position by a narrow shelf attached to the walls at the standard height of the window sills, and working accommodation is provided by tables of the same height, which are arranged in accordance with the needs of the work in progress. In the physics department stout battens are screwed to the walls at two different heights from the floors and the gas connexions and any apparatus which is to be mounted for a considerable time are attached to these battens. Fume cupboards, where necessary, are built into the window spaces, and mounted on wide concrete shelves covered with Ruabon tiles, the draught being induced by gas-burners placed in the flues at the floor level. Bright metal taps and electric switches have been avoided entirely so as to minimise the labour of cleaning.

The work of the botanical department is chiefly microscopical, and special attention has been given to various forms of artificial illumination. Each microscopist has at his disposal two gas leads, a small sink, an electric power point for microscope illumination, an electric lighting point for bench lamps, and low-voltage currents from overhead wires for warm-stage work and incidental illumination. A fire-proof and sterilisable room is reserved for bacteriology, and contains electric incubators and sterilisers mounted on concrete benches, and a gas autoclave under a ventilating hood. The department has a very large number of samples of cultivated and semi-wild varieties of cotton, and obtains further material for study from an experimental greenhouse in which about 300 cotton plants can be grown at one time. The physics department is fully equipped for research into the physical and mechanical properties of single cotton hairs, carded cotton, slivers, yarns, and fabrics. Each room is well supplied with electric power points, and is wired for six independent circuits from the battery. Two of the rooms, having concrete floors paved with wood blocks, are reserved for experiments with delicate pieces of apparatus which demand freedom from vibration. The main chemical laboratory, 40 ft. × 30 ft., is a very bright room with walls covered with white tiles up to a height of 8 ft. Furnaces, thermostats, and large pieces of apparatus are accommodated on a tiled, concrete shelf, and a special bench is reserved for distillations. The working benches, 27 ft. long, are made of pitch-pine with teak tops. Large glazed sinks are provided at each end, and the drainage from the taps and filter-pumps which range along the benches is taken by glazed channels. All the sinks discharge into loose mixing traps before emptying into the drains.

The importance of the subject of colloids for the cotton industry has been recognised by the creation of a separate department of colloid chemistry and physics. The three rooms are well equipped for physico-chemical research, one with a concrete floor being reserved for experiments which demand freedom from vibration or cause chemical fumes. Special accommodation for optical work is provided in a large room which has the roof lights completely obscured, the windows fitted with roller blinds, and all the walls, woodwork, and furniture painted a dead black. One corner of this room has been partitioned off and fitted as a photographic dark room, both parts being ventilated by a light-tight electric fan.

The coach-houses and stables of the estate have been converted into workshops for the construction and repair of instruments used in the laboratories and for the general maintenance of the Institute. Ample accommodation has been secured for smith's and carpenter's work and general machining on the ground floor, and for a scientific glass-blower above. These experimental workshops have already proved to be of enormous value to the Institute in equipping the new laboratories and making new devices for the testing of cotton yarns.

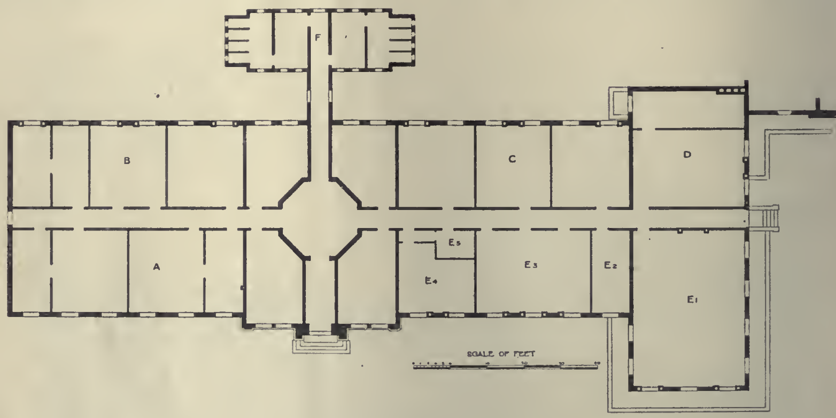

Fig. 2.—Ground Plan of New Laboratories.

A. Department of Physics.
B. Department of Botany
C. Department of Colloids
D. General Stores.
E_1. Main Chemical Laboratory.
E_2. Balance Room.
E_3. Unoccupied.
E_4. Optical Room.
E_5. Photographic Dark Room.

Below D is the boiler-house, and under E_1 a machinery room.

The National Institute of Industrial Psychology

A LARGELY attended meeting of the National Institute of Industrial Psychology was held at the Mansion House, London, on March 27, at which the principal speakers were Viscount Haldane, Mr. W. L. Hichens (Chairman of Messrs. Cammell Laird & Co., Ltd.), and Dr. C. S. Myers (Director of the Institute). The chair was occupied by Mr. H. J. Welch (Director of Messrs. Harrisons and Crosfield, Ltd., and Chairman of the Institute). The following resolution, moved by Dr. Myers and seconded by Mr. Hichens, was carried unanimously:

"In view of the present serious economic situation and of the necessity to reduce costs of production and to increase the total national output, this meeting is of the opinion that: (*a*) a more complete and scientific development of the nation's human resources and a reduction of wasteful and misapplied energy are matters of urgent national importance; (*b*) the methods adopted by the National Institute of Industrial Psychology have been shown to reduce costs of production, to promote the development of individual ability, to eliminate unnecessary effort and fatigue, and to improve the health and well-being of the worker; (*c*) it is imperative that a national fund should be immediately established to enable the institute to extend its sphere of usefulness and to continue the necessary researches into the scientific problems involved."

The following letter was read from Mr. Seebohm Rowntree: "I am sorry I cannot be present, for I should have been glad of an opportunity to speak of the services of the institute to the cocoa works at York. We have felt for some time that benefits would accrue if some of the human factors affecting efficiency were studied on a more scientific basis. . . . It was a great advantage to be able to turn to an institute like yours and to secure from you not only a trained worker to make actual observations among the workmen, but the services of a skilled psychologist to direct him. It has shown us how important are the researches still to be made in our own factory by psychological experts."

Mr. Harry Salmon (Managing Director of Messrs. J. Lyons and Co., Ltd.), in proposing a vote of thanks to Viscount Haldane for his address, expressed his pleasure and satisfaction at the work carried out by the institute in the factories and depots of his firm. The output of the packing department of the chocolate factory had been increased by over 35 per cent., and at the same time the amount of effort and fatigue of the workers had been reduced. Similar results were being obtained in other departments of the firm.

Dr. Myers emphasised the value to the employees of the institute's work. Many workers, he said, have expressed their gratitude spontaneously to the investigators for the reduced fatigue felt at the end of the day. The form of the daily output curves before and after the investigations has actually demonstrated the reduction in the workers' fatigue.

The institute, he said, also aims at guiding the young worker in the choice of his occupation, submitting him to detailed examination by applying to him a series of mental, physical, and medical tests, and considering the results in conjunction with school records. These tests serve also to guide the employer in selecting the most capable applicant for a vacant post. They are not intended to replace the ordinary interview, but to supplement it by the measure they afford of the candidate's general intelligence, and of his endowment with the special abilities required for the particular job. The institute has already, thanks to the investigations of Mr. Cyril Burt, formulated satisfactory tests for shorthand writers and typewriters. Mr. Muscio's tests for selecting compositors, published by the Industrial Fatigue Research Board, have proved equally valuable.

In the United States numerous bureaux of vocational guidance are scattered over the whole country. Occupational tests are to-day being applied in America for the selection of sales clerks, proof-readers, clerical workers, inspectors, assemblers, and other types of factory workers. Mental tests have been introduced in place of, or as complementary to, the ordinary entrance examinations in several important universities of America. At the Carnegie Institute of Technology in Pittsburgh (in the University of which there are over 2000 students of psychology) the Bureau of Personnel Research is maintained financially by a number of industrial and commercial firms, who thus obtain information relating to the selection, training, organisation, and supervision of their personnel. Single firms or groups of firms arrange with the Carnegie Institute for special research on the problems arising in their factory, office, sales, or executive organisation. Instruction and research on vocational psychology are carried on in most of the American universities.

In Barcelona, the Institute of Vocational Guidance is supported entirely by the city and by the province of Catalonia. Over a thousand applicants for advice pass through its hands every year. In Brussels a similar rate-supported vocational guidance bureau is doing most valuable work, abolishing the huge number of occupational misfits and thus reducing not only the vast expense of a needlessly large labour turnover but also the overstrain and unhappiness of the misguided worker. In Germany laboratories concerned with industrial psychology and physiology have been established in Berlin, Frankfurt, Leipzic, Munich, and other large centres. The Allgemeine elektrische Gesellschaft, the Osram Company, the Berlin Tramways, Siemens and Halske may be mentioned among the firms which have availed themselves of the services of such institutes, especially in the selection of workers in their principal departments. It is stated that during twelve months the Grosser Berliner Strassenbahn has saved over twelve million marks as a result of the application of vocational selection, proper training based on motion study, etc. Indeed, Germany hopes to secure a lead in commerce and industry by paying attention to their *human* aspect, just as in pre-war days she advanced by paying attention to their *material* aspect. Her trade unions are likewise recognising the value of vocational guidance and of systematic training in approved methods of work.

Viscount Haldane, in the course of an eloquent address, stated that there was no problem more menacing than that of unrest arising out of the relations of Labour to Capital. We had reached a stage at which the merely mechanical work was being done more and more by the machine, while the worker was becoming more and more engaged in the directing of the machine. In other words, mind was becoming of ever-increasing importance; indeed it was not capital that created wealth, nor labour, but mind. One of the objects of the institute was, so far as possible, to relieve labour from the feeling that men and women were only machines. The aim of the institute was not to secure increased output at all costs to the worker, but to improve the mental, physiological, and physical conditions under which he worked and by this means to increase his efficiency. We were beginning to realise that the workman,

although he is not a machine, needs to be studied with the same scientific care and methods as are now applied to a machine, and within twenty years, he imagined, the expert in psychology and physiology would be at the elbow of every manager of a great business. If this were done we should have taken a step towards securing the contentment of the workers, because they would, at the end of their day's work, be fresh enough to turn their attention to that spiritual refreshment and knowledge which would give them the full meaning of life.

Gas Cylinders Research.

THE first report of the Gas Cylinders Research Committee has just been published by the Stationery Office. The Committee was appointed in 1918 to inquire into the whole question of cylinders for the storage and transport of compressed gases other than acetylene, but the present report deals only with the material for cylinders for the so-called permanent gases which are not liquefied at the pressures prevailing in the cylinders. The main question under discussion was the advisability of using steel of higher carbon content than has hitherto been permitted in this country, the regulations based on the recommendations of the 1895 Committee requiring that the carbon should not exceed 0·25 per cent., whilst in America the carbon may be as high as 0·55 per cent. The railway companies favour the continuance of this restriction, arguing that the immunity of this country from cylinder accidents as compared with foreign countries points to the desirability of using only low-carbon steel. On the other hand, it is shown that cylinders of steel containing 0·43-0·48 per cent. of carbon have given perfectly satisfactory tests at the National Physical Laboratory, and that such cylinders are at present carried by road, whilst the railways conveyed a large number of hydrogen cylinders of this composition during the war under an indemnity from the Admiralty.

The Committee was not able to arrive at a unanimous decision. Eleven of the members sign the main report, in which steel of the higher content in a normalised condition is recommended as an alternative material, the stress tests and tests for toughness being specified. The chairman, Prof. H. C. H. Carpenter, and the scientific members of the Committee are agreed on this point. The dissenting member, Mr. J. H. B. Jenkins, is of opinion that high-carbon steel is not only less tough, but also more liable to variations in quality than mild steel, and that the saving in weight which would be effected by the change is too small to justify even a slightly increased risk of accident. The report contains a long account of mechanical tests and microscopical examinations, and will be found of interest by all steel metallurgists, whether they are concerned with the immediate problem or not.

University and Educational Intelligence.

ABERDEEN.—At the spring graduation ceremony on March 30 the honorary degree of doctor of laws (LL.D.) was conferred upon Prof. T. W. Griffith, Professor of Medicine, University of Leeds; Mr. John Masefield; and Dr. C. H. Turner, Dean Ireland's Professor of Exegesis, Oxford. The following higher degrees were also conferred. *Science: D.Sc.*, G. P. Hector, Agricultural Department, Dacca, India. Thesis—"Studies in the Botany and Genetics of Rice." *Medicine: M.D.*, F. W. C. Brown. Thesis—"A Critical Investigation into the Thermal Death Point of the Tubercle Bacillus in Milk, with Special Reference to its Application to Practical Pasteurisation." J. G. Danson. Thesis—"Anaphylaxis: its Relationship to Asthma and Hay Fever." M. Y. Garden. Thesis—"Observations on the Treatment of Diseases of the Lungs and Pleura by Artificial Pneumothorax." R. D. Lawrence. Thesis—"The Estimation of Diastase in Blood and Urine and its Diagnostic Significance." *Ch.M.*, Dr. W. Brander. Thesis—"Spontaneous Rupture of the Pathological Spleen."

LONDON.—The following doctorates have been conferred:—*Ph.D.* (*Science*) on Mr. J. Mould for a thesis entitled "The Properties of Dielectrics, including the Variations of Dielectric Constant with Frequency, the Energy dissipated therein and the Variation in Conductivity," and on Mr. G. Sheppard for a thesis entitled "Contributions to the Geology of Southern Alberta and Saskatchewan, Canada, with detailed reference to the Stratigraphy and Structure of the Foothill Belt and its Associated Areas"; and *Ph.D.* (*Economics*) on Bal Krishna for a thesis entitled "Commercial Relations between India and England."

The Lindley Studentship, of the value of 120*l*., offered every third year, will be awarded to assist research in physiology in the physiological laboratory. Candidates should submit a statement of qualifications and the mode of research proposed to the Academic Registrar by May 1.

Three Research Studentships for post-graduate work, of the value respectively of 175*l*., 105*l*., and 75*l*. (with remission of school fees in addition), and available for two years, will be awarded in July next by the London School of Economics and Political Science. Applications, upon a special form obtainable from the director of the school, Houghton Street, W.C.2, must be sent in by, at latest, May 31.

MANCHESTER.—A Fellowship for the encouragement of research in preventive medicine has been instituted in memory of the late Auguste Sheridan Delépine, professor of public health and bacteriology in the university from 1891 to 1921, by the addition of the emoluments of the former Junior Research Fellowships in Public Health to the interest derived from an endowment of 1000*l*., made by Dr. Charles Slater of Tunbridge Wells. The regulations which have now been approved provide for a Fellowship of 300*l*., to be offered biennially and to be open for competition by candidates who are graduates in medicine of this or any other approved university, or who hold an approved registrable medical qualification.

The Ashby Memorial Research Scholarship in Diseases of Children, value 100*l*., is being offered this session. Applications for the scholarship, with information as to the subject proposed for investigation and the qualifications of the candidates, should reach the Internal Registrar of the university before June 30.

WE referred in these columns on March 6, p. 325, to a scheme put forward by the Colston University Research Society, of Bristol, for the establishment of Colston Research Fellowships in the University of Bristol. Already the Society announces that Messrs. J. S. Fry and Sons, Ltd., Messrs. E. S. and A. Robinson, Ltd., and Messrs. C. Thomas and Bros., Ltd., have each promised to contribute the 150*l*. annually necessary to found Fellowships. It is to be hoped that the lead given by these firms will be quickly followed by other local manufacturers.

Calendar of Industrial Pioneers.

April 7, 1898. Otto Baensch died.—For nearly fifty years Baensch was in the State service of Germany and did important work in connection with the navigation of the Elbe, the Upper Rhine, and the famous Kaiser-Wilhelm or Kiel Ship Canal.

April 8, 1893. Vice-Admiral E. Paris died.—Joining the French Navy in 1822, Paris was one of the first naval officers in France to study steam navigation. He wrote manuals on mechanics and a treatise on screw propulsion, and contributed papers to the Institution of Naval Architects, of which he was elected an honorary associate.

April 9, 1870. Thomas Joseph Ditchburn died.—A pioneer builder of iron ships, Ditchburn received his training in Chatham Dockyard and assisted Sir Robert Seppings in some of his experiments. He afterwards was manager for Fletcher and Fearnall, and then with Mare established the first iron shipbuilding yard on the Thames. In 1846 he built the only iron sailing man-of-war ever in H.M. Navy, H.M.S. *Recruit.* Ditchburn later on founded the famous Thames Iron Works at Blackwall, where during ten years he constructed some 400 vessels.

April 9, 1877. William Gossage died.—A great industrial chemist and inventor, Gossage began life as a druggist's assistant. In 1830 he assisted to found an alkali works at Stoke Prior, Worcestershire, and six years later he patented his well-known condensing tower which prevents the escape of hydrochloric acid gas; an invention "which saved from extinction a trade, the growth of which has contributed to the nation's prosperity." Gossage engaged in copper smelting and other enterprises and also became the largest manufacturer of soap in the world.

April 10, 1903. Horace Bell died.—Entering the public works department of India in 1862, Bell rose to be Engineer-in-chief of the Survey of the Great Western Railway of India and consulting engineer for the State railways.

April 11, 1822. Ralph Dodd died.—The projector of a tunnel beneath the Thames between Tilbury and Gravesend, Dodd was a civil engineer and was known for his writings on canals and on the water supply and docks of London; he was also a promoter of steam navigation. He died just a hundred years ago from injuries sustained by a boiler exploding.

April 11, 1847. Charles Holtzapffel died.—The son of a German toolmaker who settled in London in 1787, Holtzapffel became an expert mechanician, and in 1843 published a valuable work entitled "Turning and Mechanical Manipulation." He was a member of the Council of the Institute of Civil Engineers.

April 12, 1840. Franz Anton von Gerstner died.—Like his father a mathematician and engineer, Gerstner from 1818 to 1825 was professor of practical geometry in the polytechnic in Vienna, and was one of the earliest continental railway engineers. He constructed the railway from Budweis to Linz, and in 1834 built the first Russian line, that from St. Petersburg to Czarskoeselo. He died in Philadelphia, whither he had gone to study the railways of America.

April 12, 1898. Aimé Claude Alfred Girard died.—A distinguished French chemist, and a member of the Institute, Girard in 1871 succeeded Payen in the chair of industrial chemistry in the Conservatoire des Arts et Metiers. E. C. S.

Societies and Academies.

LONDON

Royal Society, March 23.—Sir Charles Sherrington, president, in the chair.—Sir Richard **Glazebrook**: Specific heats of air, steam, and carbon dioxide. The values for the specific heats of these gases below 1000° C. given recently by Womersley are higher by 5-10 per cent. than those which follow from the results given by Holborn and Henning.—A. E. H. **Tutton**: (1) Monoclinic double selenates of the manganese group. The manganese group of double selenates of the isomorphous series $R_2Mn(SeO_4)_2 \cdot 6H_2O$ includes only three salts, those in which R is rubidium, cæsium, and ammonium. Optically these salts are precisely in line with those for analogous salts of other groups, so that if the potassium salt could be obtained, it would be the first member of a progressive series, and the general law of progression of the crystallographic properties with the atomic number of the alkali metal would be obeyed rigidly. The volume and edge-dimensions of the space-lattice cells of the crystal structures of ammonium manganous selenate hexahydrate and rubidium manganous selenate are nearly identical. Similar facts obtain for all analogous ammonium and rubidium salts throughout the whole isomorphous series, as well as for the rhombic simple sulphates themselves. (2) Monoclinic double selenates of the cadmium group. Crystals of the ammonium salt, $(NH_4)_2Cd\ (SeO_4)_2 \cdot 6H_2O$, which were sufficiently transparent in parts for optical use were obtained on very keen frosty nights. The potassium salt appears to be incapable of existence, its limit being probably below 0° C. Crystals of the rubidium or cæsium salt were obtained during the coldest nights of January, but they were quite opaque, so that only goniometrical measurements were possible. The results are in complete accord with those from other, complete groups.—F. A. **Freeth**: The system: $Na_2O—CO_2—NaCl—H_2O$. The system is arbitrarily considered as composed of two four-component systems, namely:—$Na_2CO_3—NaHCO_3—NaCl—H_2O$, and $Na_2CO_3—NaOH—NaCl—H_2O$. Determinations have been made at 0°, 15°, 20°, 25°, 30°, 35°, 45°, and 60° C. A general treatment is given showing how the composition and quantities of the stable phases from any mixtures of the components may be deduced.—M. A. **Catalán**: Series and other regularities in the spectrum of manganese. Flame-arc, arc and spark spectra of manganese have been observed and new series lines traced. Series belonging to the spectrum of the neutral atom are (*a*) a system of triplet series; (*b*) a system consisting of narrow triplets; and (*c*) a system of narrower triplet series running parallel to the preceding system. Intercombination lines between the two first systems appear as two lines very prominent at low temperatures. The calculated ionisation and resonance potentials of manganese are 7·4 volts and 2·3 volts. Diffuse triplets in the spectrum of the ionised atom are composed of nine lines. At different temperatures, groups of lines of the same character and related by very exact numerical separations ("multiplets") have been identified. The neutral atom of manganese probably has two electrons in the outermost ring, and when it loses one electron and becomes ionised, another electron comes out to the ring. Thus, the spectra of neutral and ionised atoms would be similarly constituted in accordance with observations.—D. W. **Dye**: Calculation of a standard of mutual inductance and comparison of it with the similar laboratory standard. The windings of the primary helices and the secondary overwound coil of a Campbell type of mutual inductance standard were measured in terms

of the length standards of the N.P.L. and the value in absolute millihenries has been calculated. Comparisons with the similar laboratory standard at a frequency of ten cycles per second showed that the ratio of the calculated values of the two standards was in agreement with the ratio of the experimentally compared values to an accuracy of 5 in 10^6.—P. E. **Shaw** and N. **Davy**: The effect of temperature on gravitative attraction. Results with a torsion balance of the Boys-Cavendish type indicated a temperature effect of gravitation of about 1×10^{-5} per 1° C. With similar apparatus modified to eliminate small mechanical movements caused possibly by the raising of the large gravitative masses to a high temperature, the effect was shown to be due to such movements reversible with temperature. The temperature effect, if any, must be less than 2×10^{-6} per 1° C. The mean effect observed is a very small diminution in attraction as temperature rises.

Zoological Society, March 7.—Sir Sidney F. Harmer, vice-president, in the chair.—N. S. **Lucas**: Report on the deaths which occurred in the Society's Gardens during 1921.—R. **Broom**: On the temporal arches of the Reptilia.—F. V. **Urich**, H. **Scott**, and J. **Waterston**: The bat-parasite *Cyclopodia greeffi*, and a new species of hymenopterous (Chalcid) parasite bred from it.—S. V. **Montgomery**: Direct development in a Dromiid Crab.—F. **Balfour-Brown**: The life-history of the water-beetle, *Pelobius tardus*, Herbst.

March 21.—Dr. A. Smith Woodward, vice-president, in the chair.—P. Chalmers **Mitchell**: Monkeys and the fear of snakes.—G. **Blaine**: Notes on the zebras and some antelopes of Angola.—R. I. **Pocock**: On the external characters of some Histricomorph Rodents.—H. R. **Hogg**: Some spiders from South Annam.

Physical Society, March 10.—Dr. Russell, president, in the chair.—R. L. **Smith-Rose**: On the electromagnetic screening of a triode oscillator. The most complete method of screening a valve set is to enclose it in a hermetically sealed box made of metal of suitable thickness for the frequency used. The smallest crack allows a detectable amount of the high-frequency energy to escape. Iron is far more effective than copper of the same thickness in preventing direct penetration of radio-frequency magnetic fields through the metal.—H. P. **Waran**: A new form of high vacuum automatic mercury pump. The pump, based on a modified Sprengel action, works automatically, the mercury being removed from the lower to the upper reservoir mixed with a current of dry air which is sucked through a side tube by a filter pump. An intermediate reservoir in the middle of the fall tube, kept automatically exhausted by the Sprengel action in the lower fall, allows the upper half to exert a positive exhaustion for every pellet of mercury falling down. The absence of compression in the first fall makes it possible to use the maximum bore for the fall tube. Less than a pound of mercury is required to operate the pump.—W. N. **Bond**: Viscosity determination by means of orifices and short tubes. General expressions for the end-corrections obtained by the method of dimensions are employed in plotting the results of experiments on the flow of mixtures of glycerine and water through pairs of tubes of equal diameter, but of different lengths. The conditions that the flow at the ends may be purely viscous and equations for determining the viscosity are given.

Royal Meteorological Society, March 15.—Dr. C. Chree, president, in the chair.—E. M. **Wedderburn**: Seiches; and the effect of wind and atmospheric pressure on inland lakes. "Seiche" is the name originally given in Switzerland to quasi-tidal movements of the level of inland lakes. In 1905 the late Prof. Chrystal investigated the seiches in Loch Earn for the Scottish Lake Survey, and found that microbaric disturbances were the most frequent cause of seiches. Other possible causes are heavy rainfall over part of the lake, rapid flooding and wind squalls. Earth tremors rarely cause considerable movements. The Scottish Lake Survey also discovered internal seiches of large amplitude. During autumn there is at the surface a layer in which there is little variation of temperature with depth. Below this is a narrow layer, the discontinuity layer, in which the fall of temperature is rapid, while below this again is the bottom water of the lake in which temperature variations are small. The effect of wind blowing along a lake is to accumulate the warm surface water at the lee end, so that the discontinuity layer is displaced from its normal horizontal position. When the wind moderates a standing oscillation commences at the discontinuity layer. The period of oscillation depends on the difference of density between these layers; the amplitude may be several feet, without causing measurable disturbance of the level of the free surface.

CAMBRIDGE.

British Mycological Society, March 18.—Mr. F. T. Brooks, president, in the chair.—Mrs. M. N. **Kidd**: Diseases of apples in storage. Moulds attacking apples in storage show a definite sequence and cause a different amount of loss. Physiological diseases are of considerable importance. Scald and probably others can be completely controlled by wrapping the fruit in specially prepared paper.—J. **Line**: Parasitism of *Nectria cinnabarina*. This fungus is associated with a characteristic wilting of apparently healthy branches, the wood of which is brown to green and occluded with fungal hyphæ. Pure cultures of the fungus were incapable of establishing the hyphæ in living wood or cortex but succeeded on artificially killed plants, and finally were able to pass into healthy wood.—K. C. **Mehta**: Observations on the occurrence of wheat rusts near Cambridge. *Puccinia graminis* does not overwinter by uredospores nor by mycelium inside the host plant; its recurrence is explained only through fresh infection by æcidiospores produced on Barberry. In *P. triticina* and *P. glumarum* viable uredospores can be found during the greater part of winter, and there is conclusive experimental evidence that these rusts can overwinter by means of mycelium inside the host plants.—F. T. **Brooks** and C. G. **Hansford**: Mould growths on cold store meat. Meat from the southern hemisphere showing mould growths was investigated. Some of these fungi, particularly *Cladosporium herbarum* ("black spot"), can develop at -6° C.; other moulds grow readily at temperatures about freezing-point. At several degrees above this, bacterial growth is so active as to suppress the moulds. The fungi are only superficial and, unless accompanied by putrefactive bacteria, do not render the meat unfit for food.

DUBLIN.

Royal Dublin Society, March 28.—Dr. J. A. Scott in the chair.—J. J. **Nolan** and J. **Enright**: Experiments on the electrification produced by breaking up water, with special application to Simpson's theory of the electricity of thunderstorms. Different samples of water were tested. The purer water gives higher charges, the difference being very great for small degrees of breaking-up. With more complete pulverisation the charge produced tends to be

independent of the purity. It is found that the purer water can be broken into finer drops. Charges are obtained about ten times as great as any reported previously. The probable charge produced by the natural breaking up of a rain-drop of 4 mm. diameter is 0·2 e.s. unit per c.c.

EDINBURGH.

Royal Society, March 20.—Prof. F. O. Bower, president, in the chair.—Address by Sir Charles **Sherrington**: Some points regarding present-day views of reflex action. More attention is being paid now than formerly to the intimate nature of the processes in the nervous centres during reflex action. The question has been raised as to whether the essential elements of reflex action as unfolded in the reflex centre itself contain any which are fundamentally different from the properties shown by simple peripheral nerve-muscle preparations. The resemblance between the neuro-muscular junction and the synapse suggests that the latter, like the former, is a junctional region exhibiting decremental conduction of the nervous impulse. Then much of the summation observable in the nervous centre could be accounted for by such timing in the sequence of centripetal impulses that the successive impulses fell in the conducting path at such frequency as to coincide with the period of supranormal phase in the conducting fibre. The larger impulses thus resulting would pass through the decremental block that suffices to extinguish smaller ones. A somewhat slow frequency of stimulus rhythm would thus succeed in making a stimulus effective which had been at the outset ineffective. Conversely a frequency of serial stimuli, each singly effective, but so timed as to follow one upon another at such interval as to fall within the period of relative refractory phase of the precedent impulse, would lead to impulses of subnormal extent. These on arriving at a region of decrement, a synapse, would fail to pass. A neurone occupied by such subnormal impulses would form a complete inhibitory block to any reflex arc of which it formed a link. Thus central inhibition could be established by successive impulses, the interval between which lay outside the period of absolute refractory phase but not so far outside as to escape that of relatively refractory phase. Lucas offers an explanation of reciprocal innervation by such rhythmic impulse adjustments as involve interference of impulses of this nature. By invoking changes in the degree of decrement in the decrementally conducting regions the reversal of reflex action can be explained. Thus A. Forbes accounts for the changing of reflex excitation into reflex inhibition by assuming that the intensity of decrement is increased by such agents as chloroform and ether. The similar reversal by fatigue lends itself to a similar explanation. Such properties, observable in the simple nerve-muscle preparation itself, can be made to explain the main essential features of action of the nerve-centres.

PARIS.

Academy of Sciences, March 6.—M. Emile Bertin in the chair.—The secretary announced the death of M. Max. Nœther, correspondent for the section of geometry.—G. **Julia**: New applications of conformal representation with functional equations.—H. **Villat**: A new problem concerning analytical functions and conformal representation. — R. **Lagrange**: The application of varieties of order p in an x space of n order.—B. **Gambier**: Point correspondence deduced from the study of the three fundamental quadratic forms of two surfaces.—A. **Planiol**: Organic yield of internal combustion motors.—G. **Camichel**: Surfaces of discontinuity.—C. **Nordmann** and **Le Morvan**: Observation of a singular phenomenon presented by the star θ of the Great Bear. From its spectrum, this star should belong to the solar type, but the intensity distribution in its spectrum corresponds with an effective temperature near that of the very hot hydrogen stars.—G. **Prévost**: Determination of the coefficients in the development in Laplace polynomials of a function of two variables.—M. **Labussière**: The geometrical existence of a general invariant of pencils of rays refracted according to Descartes' law, and its applications to geometrical optics and to radiation.—E. **Belin**: The telegraphic transmission of photographs, drawings, or manuscripts. The original is converted into a relief photograph on bichromate gelatine paper, and a stylus connected with a microphone is moved over this relief. Special arrangements are described for ensuring the synchronism of the transmitting and receiving mechanism. The efficiency of the apparatus has been proved by trials in America and in France.—G. **Claude**: The elimination of the heat of reaction in the synthesis of ammonia at very high pressures.—G. **Chaudron** and G. **Juge-Boirard**: The estimation of sulphur in iron pyrites. In the method in current use (solution in aqua regia) some sulphur occasionally separates. It has been found that by allowing the reaction to proceed at the ordinary temperature for 12 hours this error can be avoided. — H. **de Pommereau**: The reduction of ethyl benzoate and of some other benzene compounds by sodium and absolute alcohol. With ethyl benzoate the chief product is tetrahydrobenzylic acid, with a small proportion of tetrahydrobenzyl alcohol as a secondary product.—M. **Sommelet** and J. **Guioth**: The formic hydrogenation of the quaternary salts of hexamethylenetetramine. Hexamethylenetetramine chlorbenzylate boiled with formic acid gives a slow evolution of carbon dioxide. When gas ceases to be evolved, dimethylbenzylamine, $C_6H_5 \cdot CH_2 \cdot N(CH_3)_2$, can be isolated, in quantity corresponding with 60-70 per cent. of the theoretical yield.—A. **Allix**: Observations on relief sculpture by ice.—A. **Guilliermond** and G. **Mangenot**: The signification of the reticular apparatus of Golgi. It has been suggested that Golgi's apparatus has no real existence in the living plant and is caused by the preparation and staining of the section. With barley root as material, Golgi's experiments were repeated and confirmed, using not only Golgi's method, admittedly open to objection, but also the more certain technique of Cajal and Da Fano.—P. **Georgévitch**: The origin of the centrosome and the formation of the spindle in *Stypocaulon scoparium*.—Mme. A. **Pruvot**: A new and remarkable type of Gymnosome (Loginiopsis). A description of a new type of Gasteropod collected during the voyages of the Prince of Monaco in the region of the Azores. At the point where the mouth is usually situated this animal carries an appendix, in length about one-third that of the body. This is expanded near the summit into three fleshy lobes.—F. **Maignon**: The utilisation of the tissue diastases for the determination of the organ, the functional insufficiency of which is the cause of a pathological state. The application of this clinical method to the study of the physiological *rôle* of certain organs. Basedow's disease was proved to be caused not by the condition of the thyroid gland alone, since a mixture of diastases from the thyroid, ovary, and suprarenal glands was required to abate the symptoms. Eczema yielded to treatment with hepatic diastases, either alone, or mixed with diastase from other organs.—J. **Benoit**: The physiological conditions relating to the periodic nuptial adornment in birds. There is a close connection between the

state of the testicular interstitial gland and the state of the nuptial adornment (change in colour of plumage). There is no such connection between the nuptial adornment and the intratubular seminal gland.—C. **Oberthür** and C. **Houlbert**: Convergence or parallel variation in the genus Holimede.—M. and Mme. G. **Villedieu**: Contribution to the study of anticryptogamic copper mixtures. The spores of Phytophthora (potato "disease") germinate freely in solutions of copper bicarbonate, but solutions of sodium sulphate (0·18 per cent.), potassium chloride (0·15 per cent.), sodium chloride (0·15 per cent.), or potassium nitrate (0·2 per cent.) arrest completely the germination of mildew. It would appear that the presence of copper in Bordeaux or Burgundy mixtures is of doubtful utility.—M. **Aron**: The determinism of secondary sexual characters in Tritons.—P. **Nottin**: The increased solubility and diastatic degradation of the nitrogenous materials of maize. Application to yeast manufacture.

Diary of Societies.

FRIDAY, APRIL 7.

DIESEL ENGINE USERS' ASSOCIATION (at Institution of Electrical Engineers), at 3.—H. Moore: Some Characteristics of Petroleum Oil used in Diesel Engines.

LONDON SOCIETY (at Royal Society of Arts), at 4.30.—Dr. C. W. Saleeby: More Light on London: or the Coal Smoke Curse and the Restoration of Daylight.

FOOD EDUCATION SOCIETY (at Caxton Hall, Westminster), at 5.30.—Miss A. D. Muncaster, and others: Discussion on Feeding in Institutions, with special reference to School Diet.

ROYAL AERONAUTICAL SOCIETY (Students' Section) (at 7 Albemarle Street), at 6.45.—Prof. L. Bairstow: Some Aeronautical Problems of the Early Future.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—J. W. Maple: Engineering in Southern Persia.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir Ernest Rutherford: Evolution of the Elements.

SATURDAY, APRIL 8.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Ernest Rutherford: Radioactivity (6).

INTERNATIONAL COLLEGE OF CHROMATICS (at Caxton Hall), at 3.15.—E. K. Robinson: Trees: their Colours and Coloration.

MONDAY, APRIL 10.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—T. Roberts: Seven Decisive and Suggestive Scenes in the History of the Secular Contest between Conscience and Power.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore), at 5.—C. S. Fox, and others: Discussion on Dr. Heron's Report on the Geology of the Mount Everest Region.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—Dr. G. E. Moore, Prof. G. Dawes Hicks, and Miss L. S. Stebbing: Discussion on Dr. McTaggart's "Nature of Existence."

SURVEYORS' INSTITUTION, at 8.—R. Cobb: Agricultural Valuations.

TUESDAY, APRIL 11.

ROYAL SOCIETY OF MEDICINE (Therapeutics and Pharmacology Section), at 4.30.—Annual General Meeting.

ROYAL SOCIETY OF MEDICINE, at 5.—General Meeting.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—A. Millar: Galicia and its Petroleum Industry.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Dr. H. B. Goodwin: Photographic Portraiture, Pure and Simple.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—J. Wilson: A Short Account of the Genus Closterium.—L. E. Brown: Imitative and Windowed Plants.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Capt. T. A. Joyce: The Paquecha of Ancient Peru.—Miss A. C. Breton: Notes on Some Peruvian Antiquities.

ROYAL SOCIETY OF MEDICINE (Psychiatry Section), at 8.30.—Dr. B. Pierce: Recovery.

WEDNESDAY, APRIL 12.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Major W. J. S. Lockyer: The Relationship between the Solar Prominences and the Corona.

GEOLOGICAL SOCIETY OF LONDON, at 5.30.—Prof. A. C. Seward: A Collection of Carboniferous Plants from Peru.—F. W. Edwards: Oligocene Mosquitoes in the British Museum, with a Summary of our present Knowledge concerning Fossil Culicidæ.—Miss M. E. J. Chandler: The Geological History of the Genus *Stratiotes*: an Account of the Evolutionary Changes which have occurred within the Genus during the Tertiary and Quaternary Eras.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Institution of Mechanical Engineers), at 8.—A. F. Evans: Marine Engine Design as affected by Lifeboat Service Conditions.

ASSOCIATION OF ENGINEERS-IN-CHIEF (at St. Bride's Institute, Bride Lane, E.C.4), at 8.—W. H. Booth: The Artesian Wells and Geological Strata of London.

THURSDAY, APRIL 13.

OPTICAL SOCIETY (at Imperial College of Science and Technology), at 7.30.

FRIDAY, APRIL 14.

MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society).

Oxford and Cambridge and the Royal Commission.

THE original application for Parliamentary grants, which led to the appointment of the Royal Commission on Oxford and Cambridge Universities, came in 1919 from the heads of the scientific departments of Oxford. Not only were the immediate needs stated and the provision necessary to enable work to be continued, as it had been carried on before the war, but also a great development of the departments was foreshadowed with increasing difficulties in the absence of outside assistance. The Commissioners take the view that a great opportunity has come for Oxford science greatly to strengthen its position if the University and Colleges will take determined action and if funds can be made available. Far from accepting the idea that Cambridge should be allowed to develop as a "Science" University while Oxford becomes still more pronouncedly the home of the "Humanities," the Commissioners emphasise the great value of the "juxtaposition, intellectually and socially, of the best minds in diverse subjects, and the constant interaction of the Humanities and Science on one another." Accepting this point of view completely, we propose to examine their report to see how it will help the full development of science in the two universities.

Foremost in the changes recommended by the Commissioners we place for this purpose the proposals with regard to fellowships. The development in the range and character of university studies has not been accompanied by a corresponding growth in the number of college fellowships available for distinguished teachers. At Cambridge, where on the whole the newer subjects are much more strongly placed than at Oxford, there are university professors for whom no college fellowships are available. The recommendation of the Commission to create fellowships without stipend in the colleges for senior university officers—for whose stipend the university is responsible—both meets this anomaly and leaves vacancies in college fellowships for younger teachers and researchers. Many college societies will be greatly strengthened by the additions that they will thus be able to make to their body. And here we might say that it would have been a great gain to Oxford and All Souls College alike if the Commissioners had made specific provision for the inclusion of scientific studies among those to be supported by that college. Co-ordination between the University teaching by Faculties and the college teaching by tutorial supervision will be improved under the proposed scheme. The Commissioners make very few revolutionary proposals, preferring to build on the sure foundations laid by tradition and experience, and they recognise the great value of the personal contact of the college tuition in Oxford and Cambridge. But difficulties have arisen and will arise between self-governing colleges choosing their own teachers and university faculties controlling departments of study, and the Commissioners have hit on a happy solution of the problem. Colleges retain their freedom to select their own staffs but are penalised financially if a fellow elected to a teaching post is not acceptable to a University Faculty for the position of University Lecturer or University Demonstrator.

Closely tied with the proposals about official fellowships is the scheme for increasing the number of unofficial research fellowships. Coupled with an increase in the number of studentships in the Universities, which would become possible if the recommendations of the Commission as to grants is adopted, this scheme will increase greatly the development of post-graduate research work in the Universities. The Commissioners rightly lay great stress on the importance of this, but point out that it must be impracticable unless the number of teachers is increased and the directors of research are freed from some of the heavy burden of routine teaching. Each proposed reform in turn falls back upon the imperative need for financial assistance: the recommendation of a grant of 100,000*l.* a year to each university in place of the present grant—now become a recurring grant—of 30,000*l.* will have to be accepted before any large proportion of the Commission's proposals can be put into action.

Certain sections of the Commission's report do not deal directly with science but call for brief mention here. The present control of the University by Convocation or the Senate is to be greatly restricted. Congregation or the House of Residents—University

and College officers—is to be the ultimate authority, its decision being checked, in the event of a strong opposing minority, by an appeal to the larger body of non-residents. A second affirmative vote by the resident body is, however, to be decisive. Unless a minority recommendation, signed by two of the Cambridge committee, calling for immediate Parliamentary action is adopted, the position of women at Cambridge is left for decision by the new House of Residents. The Commissioners do, however, support a scheme for full membership, with restriction in numbers to 500,—essentially scheme A rejected by the Senate in December 1920. Special grants, earmarked for the women's colleges, of 4000*l.* a year to each University for a period of 10 years should be a great help to them in their present financial difficulties and a great incentive for a renewal of appeals for benefactions from the public.

Other special grants recommended are 6000*l.* a year to each University for the development of the valuable extra-mural teaching, and special arrangements are suggested for allowing selected adults to join the University without passing the entrance examination to be imposed on all ordinary undergraduates. The importance of the non-collegiate body of students is emphasised as being economical, especially suitable for certain types of students and historically the oldest form of residence in both places. The minimum cost at Oxford in 1920, in cheap lodgings of non-collegiate residence, including board and lodging, is given in the report as 65*l.*

A summary of the report has already appeared in our columns (April 1, p. 428). It is impossible to enter here into all the important questions raised as to the cost of living and the regulations as to college finance. It is equally impossible to conclude this article without reference to the enthralling historical survey of the growth of the Universities with which the report opens.

The First European Civilisation.

The Palace of Minos: A Comparative Account of the Successive Stages of the Early Cretan Civilisation as Illustrated by the Discoveries at Knossos. By Sir Arthur Evans. Vol. 1, *The Neolithic and Early and Middle Minoan Ages.* Pp. xxiv + 721 + 18 plates + plans, etc. (London: Macmillan and Co., Ltd., 1921.) 6 guineas.

THE excavations at Knossos were described by Sir Arthur Evans in detailed reports which appeared in the Annual of the British School at Athens from 1900 to 1905, and were reviewed from time to time in these columns. For years afterwards he and his adjutant, Dr. Mackenzie, were engaged in supplementary work, which involved much digging, in addition to the laboratory processes of cleaning, restoring, and classifying an enormous mass of finds. The history of successive rebuildings was unravelled, and the sequence of pottery-types verified by new trial-pits. Meanwhile discoveries on other sites have filled gaps and supplied chronological data, so that the rise of Cretan civilisation can be correlated step by step with that of Egypt. The magnificent volume before us is the first of three in which Sir Arthur Evans proposes to embody his mature conclusions; it covers two of the three main periods into which he divides the Cretan Bronze Age, and the introduction includes an outline sketch of the whole course of Minoan culture. Much of the material, as of the interpretation, is new. The book is abundantly illustrated, with plans and sections by Mr. Theodore Fyfe and Mr. C. C. T. Doll, drawings by the two Gilliérons, Mr. Halvor Bagge, and Mr. C. T. Lambert, and many excellent photographs. Even more impressive than the extent of the excavation is the skill with which it has been carried through. One wishes that this enterprise, to which the author has so long devoted his private fortune and his unrivalled insight into prehistoric problems, had been more liberally backed by public subscription.

In a notice such as this, one can touch only on a few aspects of the story which the author unfolds. He emphasises the continuity of Cretan civilisation; "from the earliest Minoan stage to the latest there is no real break such as might be naturally explained by conquest from abroad." The Neolithic strata at Knossos are 23 ft. deep, the accumulated debris of several thousand years. If the incised pottery and nude female idols recall those of Anatolian sites, this points to a common heritage rather than to intercourse between distant tribes. Over a vast area of Europe and Western Asia the same low level of rude culture had endured for many centuries without notable progress. The sudden quickening of the Cretan stock which made their island the cradle of European civilisation, came from pre-dynastic Egypt. "It may well be asked whether, in the time of stress and change that marked the triumph of the dynastic element in the Nile Valley, some part of the older population may not have made an actual settlement on the soil of Crete"—a daring hypothesis which future discoveries may confirm; the south coast and western half of the island have been little explored and certainly hold surprises in store.

Pre-dynastic stone vases seem to have reached Knossos before the accession of Menes, for which the author accepts Eduard Meyer's date, 3315 B.C.

"E.M. I.," the First Early Minoan sub-period (roughly 3400–2800), sees the transition from stone to copper implements, and from copper to bronze. On the isthmus of Hierapetra, a short cut across the island for early trade, we meet with rectangular, many-roomed houses of sun-dried bricks framed in timber, with roofs of reeds and clay such as the peasants there still use. In the next stage (2800–2400) the walls are protected with plaster containing 40 per cent. of carbonate of lime; Mr. Noel Heaton's analyses show how this developed into the fine white stucco of almost pure lime on which the fresco-painters worked a thousand years later. Knossos was now importing diorite bowls from Egypt, and imitating them in liparite brought from the Æolian Islands north of Sicily; otherwise this period is scantily represented there, and the author draws freely on the graves found by Mr. Seager at Mochlos, rich in finely wrought jewelry and vases of variegated stone. Gold eye-bandages anticipate the gold masks worn by the dead warriors of Mycenæ, and a votive double axe shows that Minoan religion had already chosen its characteristic emblem.

In "E.M. III." (2400–2100) the centre of interest shifts to the fertile plain south of Mount Ida. Sir Arthur Evans publishes a series of ivory seals found in "tholos" tombs of this region by Dr. Xanthudides, the Cretan Inspector of Antiquities, the motives of which include apes, lions, scorpions, and meander-patterns, carved by native hands, but closely related to designs current at this time in the Delta. From a similar deposit, excavated by Prof. Halbherr, came a seal on which the author recognises an adaptation of the Egyptian draught-board sign (Fig. 1) with draughtsmen of characteristic form, and he is able to assign to this period some three- and four-sided bead seals with scenes from daily life. Before the close of this period huge works were being undertaken at Knossos; a round subterranean chamber, hewn to a depth of 53 ft. below the rock-surface, and entered by a step-way curving about its circumference, shows remarkable constructive skill.

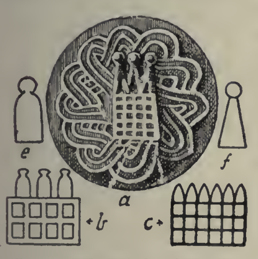

Fig. 1.—*a*, Draught-board and pieces on E.M. III. ivory signet (Fracture restored). *b*, *c*, Early types of Egyptian draught-board sign (*men*). *e*, *f*, Egyptian pieces. From "The Palace of Minos at Knossos."

Whatever their purpose, this and another "hypogæum" (as yet unexcavated) were disregarded when the First Palace was built in the First Middle Minoan period (2100–1900). It was the Age of Palaces. Alike at Knossos and at Phaistos there rose a great complex of state-apartments, sanctuaries, and store-houses; both were laid in ruins by some catastrophe, due to invasion or revolt, at the close of "M.M. II." (before 1700), and both were rebuilt with greater splendour soon afterwards, to be overthrown again at the close of "M.M. III." (about 1580). The Late Minoan phases, in which the art of Knossos attained its acme and declined, lie outside the scope of this volume.

From "M.M. I." onwards Knossos seems to dominate Crete. The buildings about the central court were planned with an eye to defence, notably the tower-like "Early Keep" which flanked the north entrance and had deep dungeons or store-pits in its basement. The neighbouring Peak-sanctuary on Mount Iuktas, frequented at this period, yielded votive offerings like those of Petsofà, above Palaikastro; these "high places" seem to have been sacred to the Mountain Mother, the supreme deity of Minoan religion, worshipped in the Palace as the Snake-Goddess. The remodelling of the Palace in "M.M. II." suggests elaborate provision for the ritual purification of those who entered it; from the first it was a sanctuary, ruled by priest-kings, who drew revenues in kind from large territories and exported oil and other produce to Egypt. The gay-coloured "M.M. II." pottery is dated within narrow limits by finds at Abydos and Kahun, and it may be that Cretan workmen settled at Kahun and worked for the Pharaohs, and even that the very ancient wharves and breakwaters off the island of Pharos, near the later site of Alexandria, which have been explored in recent years by M. Jondet, were constructed by Minoan engineers. Cretan art owed some of its technical accomplishment to this intercourse, but developed on its own lines, tending more and more to naturalism.

After the destruction of Knossos and Phaistos at the close of "M.M. II." a new dynasty took control, as the author infers from the introduction of a new linear script, not a direct outgrowth of the hieroglyphic system, and new methods of sealing; but the sacred character of the Knossian palace persisted, and a large part of the six acres which it covered was devoted to "lustral basins" (the "bath-rooms" of earlier reports), "pillar-rooms," and shrines. The state-apartments of the period, built on the hill-side east of the central court, are preserved to a height of two stories; the excavation of this region, and its reconstruction by the substitution of new beams and pillars for the carbonised ancient timbers, were feats of which Sir Arthur Evans and his staff may be proud. The elevation of the Grand Staircase (Fig. 2) illustrates the spacious dignity of Minoan architecture at its best. Of the fresco-paintings two examples are reproduced in colour, but the larger pieces are reserved for a Knossian Atlas to be published hereafter. Other colour-plates represent the faïence Snake Goddess, the famous inlaid draught-board of ivory, gold, and

crystal, and the polychrome pottery which in "M.M. II." attained a marvellous perfection of both form and design, but fell off in the succeeding period when other arts, notably that of the gem-engraver, were making rapid progress. Apparently the growing wealth of the new dynasty provided an abundance of table-ware in more precious materials, and pottery "was nothing accounted of"; the same cause led to the formation of a Palace Treasury in the west wing. Some of the magazines were walled off, and a series of lead-lined strong boxes was built under their floors. All were plundered when the palace was sacked, only scraps of gold foil and fragments of inlaid caskets being left. The author shows that the richest of the Mycenæ shaft-graves belong to this period, and that their contents, gold, silver, and faïence, may be part of the spoils of Knossos.

The book lights up many other problems; it makes known an early art of extraordinary freshness and beauty, and since it justifies in detail the "Minoan" system of classification and nomenclature, it lays a broad foundation for future research.

R. C. BOSANQUET.

Turbulence as a Meteorological Agency.

Die Zirkulation der Atmosphäre in den gemässigten Breiten der Erde. Grundzüge einer Theorie der Klimaschwankungen. By A. Defant. Pp. 209-266. (Stockholm: Geografiska Annaler, 1921.)

THE study of turbulence as an agency of direct numerical importance in meteorological phenomena had its beginning before the war in the investigations of Åkerblom Hesselberg, G. I. Taylor, Barkow and W. Schmidt, and it is not surprising that it should have been developed independently on either side of the front during the war: on one hand by Taylor, L. F. Richardson, F. J. W. Whipple, D. Brunt, and H. Jeffreys, and on the other hand by W. Schmidt, F. M. Exner, and A. Defant. On both sides there has been the recognition of a common mathematical form of transmission upward or downward, through the agency of turbulence, of various elements with numerical coefficients that can be measured without entering into the details of the process by which the transmission is effected.

With us the study has been specially useful as applied to the eddy motion recognisable in winds and fogs, which is due to the friction of the ground and to the consequent deviation of the surface wind from the geostrophic wind; while on the other side the conception has tended to the general law of "Austausch," the passage upward or downward of heat or momentum in consequence of the ascertained conditions of equilibrium of adjacent columns. Both groups in different ways have come to recognise that transference by irregular turbulent motion is a principle of very general application, and that turbulence may range step by step, perhaps discontinuously, from the ultra-microscopic scale of molecular turbulence which we measure as viscosity to the gigantic scale of the eddy motion of the great cyclonic depressions or even of the general circulation of the whole atmosphere. L. F. Richardson has expressed the generality in a manner which easily sticks in the memory:—

> Big whirls have lesser whirls that prey on their velocity;
> They again have smaller whirls, and so on to viscosity.

In course of time we may have a view of the same idea of the universality of the ways of eddy motion from the Japanese point of view. The present article is concerned with an attempt on the part of Prof. A. Defant of Innsbrück to use the turbulence of the cyclonic depressions of middle latitudes to explain the distribution of temperature over the earth's surface and suggest explanations of climatic oscillations without entering at all into the details of the turbulent motion by which the effects are produced. It is an important and suggestive chapter in a new volume of meteorological theory. It deals with *turbulente Strömung grossen Stils*, a greater scale than has been used hitherto. Its basis is an extension of Schmidt's idea of Austausch of mass, and its accompanying properties in the vertical, to the Austausch of mass in a horizontal surface along meridians in consequence of the turbulent horizontal motion which is expressed by the irregular barometric changes in middle latitudes, between 40° N. and 70° N. These are the first stages of smaller whirls on the back of the great general whirl, and we read, with some curiosity as to the further development of the next following stages, "Alle Druckstörungen pflanzen sich mit derselben Fortpflanzungs Geschwindigkeit der aussertropischen Zirkulation."

With the aid of an equation, belonging to what is now a recognised family, a formula is obtained for the normal flow of heat across a vertical square centimetre near the ground which. with an Austausch coefficient A equal to 10^8 gcm.$^{-1}$sec.$^{-1}$ gives a flow of heat northward of 100 gram calories per sq. cm. per minute. The value of A is supported by the integrated components of wind, north and south, at Potsdam, and we are allowed to infer that the general circulation of the atmosphere west to east goes on all the time and is crossed by a flow alternately north and south due to turbulence which on the average of the year gives the numerical result specified.

From that conclusion Defant proceeds to calculate the disturbance of surface temperature for latitudes north of 30° from the balance which would result from radiation alone; thence to calculate the distribution of temperature when the turbulence is taken into account and to compare the results with Hann's normal mean temperatures for successive latitudes. Finding that a uniform value for the coefficient of Austausch gives notable discrepancies, he adjusts the coefficient to bring calculation and observation into agreement, and thus arrives at the following values for A: 10^8 at lat. 30°, 5×10^8 from 40° to 65°, and $1{\cdot}7 \times 10^7$ at 85°, with intermediate values for the intermediate latitudes; agreement being thus obtained, he claims that the variation of turbulence with latitude gives a satisfactory picture of the conditions so far as he knows them.

Having thus arrived at an explanation of the steady state, he proceeds to discuss the effect of a sudden permanent increase of temperature in the intertropical belt, such as might be assumed to represent the effect of the activity of sun-spots. He finds that the Austausch would cause a corresponding change of diminished amplitude with little difference of phase in more

northern latitudes, and finally discusses periodic alterations of the three elements upon which the distribution of temperature must be based, namely, the temperature of the intertropical belt, the radiative power of the air, and the intensity of the general circulation. He thus outlines a general theory of climatic changes.

The processes of reasoning are mathematical, and are set out with exemplary clearness; in order to get numerical results a great number of assumptions are necessarily made. So long as the discussion is confined to the consideration of the earth as a whole and normal temperatures are treated as a simple function of the latitude, a good deal of liberty may be allowed in the other assumptions; but when we get to close quarters with current meteorological experience some of them will naturally need adjustment. It seems odd that in dealing with periodic changes the best known periodic change from winter to summer did not challenge the author's curiosity. It seems nearer at hand than the influence of sunspots or Brückner's cycle.

The justification for using the Austausch A as a numerical symbol of the effect of the whole irregular atmospheric motion of middle latitudes would be complete if it could be shown that its measure from time to time would do instead of the study of the motion itself. From that point of view the winds at Potsdam can be regarded only as a beginning, and not a very good one. The winds at Bergen would certainly tell a very different story. The next step appears to be a closer examination of some data for Austausch.

One more point is noteworthy. Prof. Defant is apparently under the impression that in consequence of the conservation of momentum winds of 300 m./sec. are a meteorological possibility from the occurrence of which we are saved by the turbulence of middle latitudes. What we thought to be the causes of our worst gales appear as our safeguard against being blown away completely by winds of tenfold velocity. But in our practice we have become accustomed to regard winds as inevitably related to pressure differences. Prof. Marvin, of the United States Weather Bureau, has recently pointed out that the idea of winds of 300 m./sec. is one of the common fallacies about the atmosphere that not even the *cognoscenti* have escaped, and that in face of the "geoidal slope" they could not occur, turbulence or no turbulence. It is, therefore, a little disconcerting to find that Prof. Defant deploys the power of the Austausch to destroy them: disconcerting for this reason, that we are apparently put in possession of an engine that is powerful enough to reduce winds of 300 m./sec. to 20 m./sec. if it were wanted, and it is not wanted. What then becomes of its power? Has the power of the engine been over-estimated, or has it other work to do?

It is true that Prof. Defant's remark is merely an *obiter dictum*, and has no influence upon his reasoning; but the same idea stares one in the face from the diagrams of Ferrel, J. Thomson, and others, and is quoted by more recent authors. It is time it was cleared off the field of meteorological theory.

Napier Shaw.

Forensic Chemistry.

Forensic Chemistry. By A. Lucas. Pp. viii + 268. (London: Edward Arnold and Co., 1921.) 15*s*. net.

Mr. A. Lucas, who is the director of the Government Analytical Laboratory and Assay Office, Cairo, claims that his book is the first of its kind in English, with the possible exception of a small work on legal chemistry which he published in 1920, out of which the present work has grown. In a limited sense the claim may be valid, although the distinction between forensic chemistry and forensic medicine, on which latter subject there are many well-established treatises, is one of degree rather than of kind. Hitherto works on forensic medicine have included forensic chemistry. The expert on forensic medicine has usually been a medical man with knowledge and experience of the detection of chemical substances, such as poisons, which may form the subject of criminal investigation. Strictly speaking, the two branches are, however, perfectly distinct, and there has been a growing tendency within recent years to differentiate them. The criminal who contemplates murder, for example, has far more means at his disposal nowadays than formerly. Science has furnished him with methods unknown to former generations, and these can be combated and checked only by methods of science. It was inevitable, therefore, that public security should require the establishment of a special class of expert whose duty should be the study and application of methods of detection and recognition by chemical means of the many agents and appliances which may now form the subject of criminal inquiry.

But forensic or legal chemistry, as Mr. Lucas points out, may be concerned not only with examinations for the presence or absence of particular substances, such as poisons, but with questions which are only partly chemical, as the examination of blood-stains, questioned documents, counterfeit coins, fibres and textile fabrics—in fact, any problem of criminal

investigation in which chemistry may be of service in the administration of justice and with which medicine as such may have little or no concern.

Mr. Lucas's book, as might be expected, is largely based upon his experience of the methods of the criminal of the East, who, although he may not have all the appliances of his Occidental *confrère*, is scarcely less resourceful. Indeed, some of the instances of ingenuity and cunning to which Mr. Lucas incidentally refers may be recommended to the notice of writers of detective stories. Invested with all the glamour of the Orient, they would form a new departure in that class of literature.

The book is eminently practical, although it omits details of manipulation and methods of examination to be found in standard treatises on chemical analysis. It presupposes, in fact, that the chemist who embarks on the subject of forensic chemistry is a well-trained analyst with a sound knowledge of general chemistry. At the same time, it gives in detail the special methods needed by the expert. In a short introductory chapter the author offers very wise advice on the practice of forensic chemistry, evidently based upon personal experience and a wide reading of notable trials. Legal procedure, it must be admitted, is at times eminently unscientific. It might be supposed that the practice of the law would tend to the cultivation of the scientific spirit in its practitioners, but observation shows that this is far from being uniformly the case. This fact constitutes a difficulty with which the chemical expert has occasionally to contend. The rules of conduct which Mr. Lucas lays down may enable him to meet it. The value of the expert's testimony depends largely upon the manner in which he presents it and upon the soundness and extent of knowledge with which he is able to support it. The lengths to which cross-examination may go are almost limitless, and side-issues may be developed which require wide and accurate general knowledge to deal with satisfactorily. At the same time, the forensic chemist must never forget that he is not an advocate or a partisan; his single object should be to assist the court to a just decision.

Every kind of criminal investigation with which the chemist may be called upon to deal, such as the testing of blood-stains, the analytical examination of bullets and other projectiles for firearms, of clothing, counterfeit coins, documents, explosives and explosions, fibres, finger-prints, fires and firearms, poisons and narcotics, etc., is covered in Mr. Lucas's book. As regards blood-testing in legal cases, the author rightly insists that it should be undertaken only by those who have considerable experience of the work. The sources of error are frequently many, and the issues may be most serious. The chapter dealing with this subject is an excellent example of the care and caution with which the author approaches any question of chemical jurisprudence. Dealing with projectiles, it is only necessary to recall the Monson trial to realise how much may depend upon the analytical examination of projectiles, wads, and cartridges, the number and width of marks made by the rifling of the barrel, the direction of its twist, the presence of rust, etc. As regards clothing, the author shows how the examination of a waistcoat led to the detection and conviction of a German spy during the war of 1914–18.

Counterfeit coining seems to be very prevalent in Egypt. The coins are usually struck, and many, we are told, are excellent imitations. A few illustrative cases are given, some of which display considerable ingenuity in adapting primitive appliances and apparatus intended for other purposes. The examination of suspected documents in cases of substitution or forgery may require the testing of the paper for the nature of the fibre, the recognition of water-marks, the analysis of the ink employed, the style of pen used, etc. Cases met with in Egypt evidently present difficulties not usually present in European countries.

Knowledge gained during the war has undoubtedly led to a great extension of the use of high explosives for criminal purposes, especially in the form of bombs as a means of assassination, and the chemico-legal expert is not infrequently called upon to examine them in connection with attempts at murder. Such examinations are, of course, often attended with danger, and need to be made with circumspection and care. The precautions to be taken are set out in some degree of detail. Of recent years Egypt has been particularly fruitful of instances of the kind, in which Mr. Lucas or his assistants would seem to have had ample scope for the exercise of their courage, skill, and ingenuity.

But the "tyranny of space" forbids any further attempt to illustrate the possibilities of chemistry as applied to the detection of crime. For other examples the reader may be referred to the book under review. The possibilities are, in fact, boundless. Mr. Lucas shows how the chemical examination of stains and marks, dust and dirt, even of tobacco, may afford clues which may lead to the conviction of criminals. Indeed, one rises from the perusal of his book with the feeling that the ideal forensic chemist would be a combination of Sherlock Holmes with a comprehensive compendium of general and analytical chemistry such as might be embodied in a person of whom fiction has hitherto afforded no example.

The "Index Kewensis."

Index Kewensis Plantarum Phanerogamarum. Supplementum Quintum Nomina et Synonyma Omnium Generum et Specierum ab Initio Anni MDCCCCXI usque ad finem Anni MDCCCCXV Nonnulla Etiam Antea Edita Complectens. Ductu et Consilio D. Prain, confecerunt Herbarii Horti Regii Botanici Kewensis Curatores. Pp. iii + 277. (Oxonii: e Prelo Clarendoniano, 1921.) 76*s*. net.

THERE is probably no publication which is awaited with such interest and impatience as the issue from time to time of the supplements of the "Index Kewensis." Had it not been for the interruption of the war, the list of genera and species published, or the publication of which was ascertained, in the five years 1911–15, would doubtless have been available to botanists less than six years after the second date. This delay was inevitable, but it may be assumed that Supplement 6, comprising the years 1916–20, is well on the way and will be available for workers before another five years have passed. Some names published abroad during 1914 and 1915 were not noted in time for insertion in the present supplement, but will be included in the next.

A rough estimate shows that the present volume indexes more than 33,000 species-names, and a perusal of a few columns indicates the large number and great variety of the books and periodicals which have been searched during the compilation of the work, which, so far as one can judge by inspection and trial, maintains the high standard of accuracy and completeness of the parts previously issued. It is a great help to have a note of the date of publication of the book or periodical cited; the absence of this was a disadvantage in the earlier volumes. Similarly the practice adopted in the previous supplement of not attempting to distinguish between species and synonyms, often a matter of personal opinion, has again been followed, and the work maintains its character purely of an index. Attention is directed in the preface to the fuller geographical citations as compared with previous volumes; thus in American species the name of the State follows the indication U.S.A.; in Chinese, the name of the province, and so on; this additional information is a distinct gain.

To the botanist a perusal of the columns is of special interest as marking the progress of botanical exploration generally; thus the large number of genera and species quoted as from China, especially the south-western provinces and the Philippine Islands, suggests the important work being carried on in those areas by British and American collectors and investigators. The progress of standard floristic works, such as the "Flora of Tropical Africa," or series of monographs, such as the "Pflanzenreich," is also recorded in these cases under the genera of families specially concerned.

The numerous entries under certain well-known European genera, such as Hieracium, which fills ten pages, and Rubus, which fills eight, recall the intensive study of species and their segregation, which will doubtless continue to supply material for future supplements. The many unwieldy trivial names, sometimes running into eight syllables, indicate the difficulty of finding new names for species when these run into the hundreds in individual genera. The occasional appearance of names from periodicals antedating the special period shows the great difficulty of sweeping up all the literature. Thus a harvest of new names has been supplied by Hegetschweiler's "Flora der Schweiz" (1839), previously overlooked, and the recognition of Philip Miller's "Abridged Dictionary of Gardening" (edition of 1754), in which many genera were carefully defined, necessitates the reference of some well-known genera to Miller instead of to later authorities.

In the method of citation the recommendation of the latest International Code of Rules is followed in the use of the capital letter only for species-names derived from a personal or a generic name. In the manner of production, from the irreproachable Latin preface onwards, the volume upholds the credit of the Oxford University Press.

Mental Measurement.

(1) *The Essentials of Mental Measurement.* By Dr. W. Brown and Prof. G. H. Thomson. (The Cambridge Psychological Library.) Pp. x+216. (Cambridge: At the University Press, 1921.) 21*s*. net.

(2) *How to Measure.* By Prof. G. M. Wilson and Prof. K. J. Hoke. Pp. vii+285. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1920.) 12*s*. net.

(1) ELEVEN years ago Dr. William Brown published as a thesis for his doctorate a suggestive and original monograph on the use of the theory of correlation in psychology. Later, by adding one or two chapters of introduction and two or three others on the so-called psychophysical methods, he expanded this monograph into a compact manual entitled "The Essentials of Mental Measurement." Now, in turn, after another and a longer interval, the manual itself has developed into a guinea royal-octavo volume, extensively enlarged and exhaustively revised.

The larger additions consist for the most part of a detailed series of mathematical arguments, examining what is termed the "hierarchical theory," and bringing

together the substance of important controversial papers on this subject published from time to time by Prof. Godfrey Thomson during the war. There are, however, several other new insertions. There is a long and lucid chapter on the elementary theory of probability and a shorter and more abstruse one upon skewness and heterogeneity in psychophysical data—a chapter in which, as indeed all through the volume, Prof. Karl Pearson's views and manner of approach are plainly reflected.

In the present stage of its development the book is an interesting though composite production. From the title one would expect some description of the recent methods of individual measurement—methods for assessing intelligence and for estimating the capacities and attainments of the mind. Instead we have critical prolegomena upon statistical adjuncts, and the writers have in view, not so much general mental testing, as the testing of the mental tests themselves. The book opens with a general chapter headed "Mental Measurement," which seems to promise the broad survey characteristic of a general text-book, but most of the pages in the second portion of the book, and most of the paragraphs in its two independent prefaces, are simply brilliant contributions to a special controversy. The three doctrines chiefly attacked are those connected with the name of Prof. Spearman. It is, however, highly satisfactory to learn that Dr. Brown finds elements of truth in the views that he disputes, and feels himself to be "more convinced than ever that the work of Prof. Spearman's correlational psychology is epoch-making in its significance."

The heterogeneous character of the volume has been severely criticised by at least one eminent statistician.[1] But perhaps the best defence to this criticism is the simple circumstance that at present the whole subject of mental measurement has itself arrived at a somewhat heterogeneous stage. In any case, the mixed and controversial quality of the book does not lighten or alleviate the difficulties of a topic already intrinsically perplexing. The treatment is of necessity technical. From first to last the pages of the book are dotted with algebraic formulæ and symbols, and the description of methods is at times extremely condensed. Indeed, to any but a mathematician little but the general gist of discussion can at times be comprehensible. However, a third section to the book is promised, summarising in non-mathematical language both theories and results for the general reader.

Meanwhile no research student who thinks of employing the statistical methods here described and discussed can ignore this treatise. It is, indeed, considering the intricacy of the subject, a work of great lucidity and compression, and, whether the criticisms urged against previous workers are insuperable or not, objections to their views certainly required statement at length and in detail.

(2) The volume by Prof. Wilson and Prof. Hoke is altogether different from that by Dr. Brown and Prof. Thomson. It is written for American teachers, and describes in simple phraseology some of the methods in vogue for individual measurement. The chapters consist mainly of an account of the various tests recently standardised for measuring attainments in the chief subjects of the school curriculum—reading, writing, drawing, arithmetic, and the like. A few pages are added on the measurement of intelligence and on statistical methods and terms. The book is published in the hope of encouraging the teachers themselves to apply to their classes the diagnostic methods that hitherto, for the most part, have been handled by psychologists alone. It is one of the many popular volumes that have appeared and are likely to appear upon the practical educational applications of these psychological methods.

Statistical Method.

A First Course in Statistics. By D. C. Jones. (Bell's Mathematical Series.) Pp. ix+286. (London: G. Bell and Sons, Ltd., 1921.) 15s. net.

THE needs of the student of social statistics form the prime consideration in this "First Course," but, as the author states, illustrations have been drawn from all sources, and it will serve very well as a brief introduction for students in other branches of science. The volume has been divided into two parts. Part I. is elementary in character, and in the main can be followed by a reader with little mathematical knowledge. The notions of measurement and of variables are explained, and the conceptions of the frequency distribution, of classification and tabulation are briefly discussed, and a couple of chapters follow on the simpler forms of average and the weighted mean. Dispersion comes next, accompanied by a more detailed discussion of the frequency distribution. The following chapter is on graphs, an unusual feature in this chapter being the inclusion of sections on interpolation and on supply and demand curves. A treatment of the correlation of two variables on simple lines concludes the first part of the book. Part II., though it begins simply, is of a more advanced mathematical character. The first few chapters are on probability, sampling, and probable errors. Prof. Pearson's generalised probability curves are then dealt with, and the method of moments; two chapters on the normal curve and the

[1] G. U. Yule, *Brit. Journ. Psych.*, vol. 12, pp. 100-107—an article which is itself of much importance as a contribution to the points at issue.

normal correlation surface conclude the volume. An appendix of some sixteen pages deals with a number of incidental points, and short notes are given on certain current sources of social statistics and on tables as aids to calculation.

The book seems very competently done, and we have noted few points for criticism that are worthy of individual comment.

A criticism of a general kind may, however, be made, namely, that the author has not kept in mind sufficiently carefully the type of reader whom he is addressing. The initial chapters of Part I. are written in a very simple style, adapted to a reader of little ability and practically no mathematical knowledge; but in the chapters on correlation differentiation is used, and in Part II., when Prof. Pearson's curves are explained, the reader will require a fair knowledge of and ability to use the calculus. The result is that parts of the book are beyond the elementary reader, and others almost too elementary in style for the more able student. It should, however, prove a useful addition to the small, but growing, number of books on the theory of statistics, for the same ground is not covered by any other volume. The printing and general get-up of the book are admirable, but author and editor of the series are to blame for not including an index.

G. U. Y.

Surveying for Oil Geologists.

(1) *Field Mapping for the Oil Geologist.* By C. A. Warner. Pp. x+145. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 13*s.* 6*d.* net.

(2) *Field Methods in Petroleum Geology.* By Dr. G. H. Cox, Prof. C. L. Dake, and Prof. G. A. Muilenburg. Pp. xiv+305+11 plates. (New York and London: McGraw-Hill Book Company, Inc., 1921.) 24*s.* net.

THE great increase in the demand for combined geological and topographic mapping of oil-fields has led to the issue of books to teach the rudiments of geology to surveyors and of surveying to the geologist. These two manuals belong to this group. (1) The smaller, by Warner, is written with special reference to the conditions of the central oilfields of the United States, and it includes tabular summaries of their geological sections. The geology is otherwise so elementary that no oil company would be well advised to trust to geological surveys by men whose knowledge of the subject is so limited that they would gain any help from the chapters thereon in this book. Its concise mathematical tables, simple explanations of surveying methods, instructions for the preparation of convergence maps and for the verification of oil scums on seepages, may, however, render it useful to geologists who have had no special training in oil prospecting and may be called on to take part in this work.

(2) The work by Messrs. Cox, Dake, and Muilenburg, three professors of the Missouri School of Mining and Metallurgy, is a larger work, and its geology is more advanced. The mathematical tables are fuller, and the account of geological structures may be read with great advantage by students of geology in schools which do not give much attention to the structural side of the subject. It has an admirable glossary, which explains among other facts that the term "wild-cat" in oil mining is not the same term of contempt as in metal mining, as it is applied to all well-sinking in unproved territory. This development of the term suggests that American opinion regards all oil boring in unproved ground as so speculative that the expression is used for it which the metal miner adopted for forlorn hopes and reckless gambling. In a book in which conciseness is so indispensable it seems unnecessary to have included the history of the mariner's compass and of the barometer.

Neither book gives any help in the use of fossils. The Missouri manual refers to fossils as if their evidence were too difficult for use by any but an expert; considering, however, the importance of fossils in oil work and the value of the indications often given by the simplest of palæontological evidence, some instructions how to recognise and collect fossils might usefully have been included.

The Fourth Dimension.

The Fourth Dimension Simply Explained. A Collection of Essays selected from those submitted in *The Scientific American's* Competition. Pp. 251. (London: Methuen & Co., Ltd., 1921.) 7*s.* 6*d.* net.

THE fourth dimension and non-Euclidean geometry have achieved a prominence quite unprecedented for mathematical topics. In train, bus and tram, over lunch and at the theatre, intelligent man is discussing the fundamentals of his physical consciousness. Mathematicians have sprung a surprise on the man in the street—and on one another, and the former has some reason to complain. He remembers, perhaps with pain, the tyrannical ukases of Euclid, and, if he did not acquire an enthusiastic love for the old Greek, he was at any rate pleased to think that the puzzles of geometry had been settled by something approximating to incontrovertible authority; he was grateful that he need not worry about the doctrine of parallels, or the three angles of a triangle, or about the up and

down, to and fro, right and left. Suddenly the man in the street finds himself floundering in a morass of sceptical ignorance.

How much good it would have done him if it had been impressed upon him early enough that geometry "is a matter of experiment and of experience," that it "shows what would be true if certain other things were true," if he had realised that Euclid was a guide in the interpretation of ordinary space experience, and not a royal promulgator of irrevocable decrees! He would have been spared some of the journalistic sensationalism of the past two years, and have been better equipped to think clearly and without prejudice.

Of course the fourth dimension of relativity is not the same as that suggested by the older conception of four-dimensions, although it is still a common experience to hear somebody complain that it is nonsense to suggest that time is $\sqrt{-1}$ times a length. Nevertheless this book of essays will be read with interest. The book was worth publishing if only for the clear and excellent introduction by Prof. Manning.

Some of the essays are distinctly good, although they all suffer the inevitable consequence of having a lot of information crammed into a small space. Several are impartial, others seem to look with favour on the possibility of a fourth dimension, while a few speak of it with scant respect. There is very much repetition, as is bound to be the case in such a publication, and a considerable amount of the sort of speculation that finds indications of the fourth dimension in spiritualistic phenomena, that makes the fourth dimension a constituent of life-force, that sees the fourth dimension suggested in Ephesians iii. 18, and that thinks it possible that many of the small objects each of us loses disappear by rolling out of three-dimensional space into the fourth dimension! S. Brodetsky.

Our Bookshelf.

Imperial Institute: Monographs on Mineral Resources with Special Reference to the British Empire: Petroleum. Prepared jointly with H.M. Petroleum Department with the co-operation of Dr. H. B. Cronshaw. Pp. x+110. (London: John Murray, 1921.) 5*s.* net.

A new "red" book dealing with petroleum has appeared recently as a small volume uniform with the well-known monographs of the Imperial Institute. It is a type of publication that was much needed, since it embodies in summary form the main geographical, geological and economic features of the world's oil-fields. At the present time this information is very scattered, more particularly in connection with British resources, so that a scientific discussion of the subject, at once lucid and easily accessible, forms a welcome addition to official technical literature.

The volume is divided into three sections, the first reviewing briefly the more theoretical phases of oil technology, such as the origin, migration, and accumulation of petroleum, the second dealing with British, Colonial, and mandatory resources, and the third with foreign resources. Several statistical tables concerning production of oil in various countries are included, the information under this heading being brought up to 1920 in most cases; the results of distillation of typical crude oils are given, together with certain physical characteristics. A small map of the world showing the principal oil-bearing localities and a short bibliography are appended.

A somewhat unfortunate attempt has been made to tabulate the characteristics of the oil regions of the United States, a task requiring no little care and a great deal more space than has been allocated to it; one would scarcely describe the prevalent structure of the Appalachian region as anticlinal, while the omissions in the same connection under the headings of Lima–Indiana and the Rocky Mountains are difficult to understand. With this exception, the text is remarkably good in every way. H. B. Milner.

Peoples of All Nations. Edited by J. A. Hammerton. No. 1. Pp. xxiv+112. (London: The Amalgamated Press, Ltd., 1922.) 1*s.* 3*d.* net.

This is the first instalment of a popular work to be issued in fortnightly parts which, when complete, will give an account of all the nations of the world in alphabetical order. It is a remarkable piece of journalistic enterprise. The whole work promises to be of great interest and of some considerable educational value as a work of reference for the class of reader for whom it is intended. In the present number Sir Arthur Keith contributes a foreword on the "Dawn of National Life," which deals with racial origins and the development of culture. The nations described are Abyssinia, Afghanistan, written partly by Sir Thomas Holdich, Albania, in part by Miss Durham, and Algeria. Each article is divided into three parts, of which the first deals with geography and ethnology, the second is historical, each of these being by a recognised authority, and the third gives statistical and other data. In view of the limited amount of space available, the articles are extremely well done and give the salient facts in readable and attractive form. The chief feature of the publication, however, is the illustrations, which are remarkable both in number and quality.

Tables, Factors and Formulas for Computing Respiratory Exchange and Biological Transformations of Energy. By T. M. Carpenter. (Publication No. 303.) (Washington: Carnegie Institution.) 2 dollars.

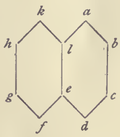
Publication No. 303 of the Carnegie Institution contains not only a number of tables for the expression of the results of gas analyses but also those of Benedict and his colleagues and of Aub and Du Bois for the estimation of basal metabolism. Some of these tables are inaccessible and all are scattered through a variety of journals and monographs, so it is a great convenience to the investigator to have the whole series in a single handy volume. This work will take its place beside "Chambers," "Barlow," and "Tables for Statisticians and Biometricians," on the shelves of most workers.

Letters to the Editor.

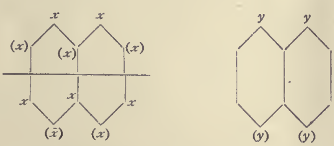
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Atomic Vibrations in the Molecules of Benzenoid Substances.

SIR WILLIAM BRAGG has recently suggested (Presidential Address to the Physical Society, Proc. Phys. Soc., 1921, 34, 33) that in the molecule of crystallised naphthalene the carbon atoms are arranged so that in the accompanying figure the centres of atoms at h, l, b, g, e, c lie in a plane, whilst those at k and a lie above the plane and those at f and d an equal distance below it.



If this were the normal stable arrangement in naphthalene and its simple derivatives, enantiomorphism would result in the case of all monosubstituted, and in the majority of the higher substituted compounds, the special examples of symmetry being obvious on inspection. Since, however, all the available evidence tends to show that the molecules of naphthalene derivatives are identical with their mirror images, it follows that the structure suggested by Sir William Bragg represents a phase of an oscillation of the relatively unrestricted molecules of the fused or dissolved substance in which the pairs of carbon atoms k, a and f, d appear alternately above and below the plane containing the six remaining atoms. At the first glance such a process appears peculiar and unsymmetrical, but this objection disappears when it is noticed that an identical result is obtained if all the atoms are supposed to be in motion in such a way that adjacent atoms move in opposite directions and to an equal distance from the plane of the original ring. If the component perpendicular to the plane of the ring is x, then the condition arrived at is shown below, x and (x) signifying, respectively, above and below the plane of the ring.



By rotating about the axis figured, the second position is obtained with six atoms in the plane of the original ring and four arranged as indicated ($y>x$ and $<2x$). A similar vibration of the phenanthrene molecule would demand in the case of an isolated phase that the atoms lie in two planes parallel with that of the original ring, and also in four parallel planes containing carbon atoms to the number of two, six, five, and one, respectively. The above argument is circular to the extent that the naphthalene configuration was partly derived by analogy with the hexagonal rings of the graphite layers, but the point is that if independent evidence is forthcoming that an individual naphthalene molecule in a crystal has the arrangement of atoms put forward by Sir William Bragg, then at the same time at least one mode of vibration of the benzenoid molecules will be clearly indicated.

R. ROBINSON.
Chemistry Department, The University, St. Andrews.

Transport of Organic Substances in Plants.

IN a letter in NATURE of February 23, p. 236, under the above title, Prof. H. H. Dixon and Mr. N. G. Ball put forward the view that the wood of the vascular bundles provides the main path for the removal of the organic materials formed in foliage leaves to places of storage or conversion, the structure, form, and arrangement of the bast (phloem) being regarded as precluding any important longitudinal transmission within it.

I venture to doubt if the view that the phloem may serve as an important carbohydrate-conducting tissue merits such summary dismissal as the writers of the letter would appear to suggest.

In the first place, it is somewhat misleading to state that this belief . . . "seems to be based entirely on ringing experiments," unless this statement is intended to apply only to the "older writers." In an article on the Translocation of Carbohydrates (*Science Progress*, October 1910, January 1911) I attempted to bring together the available evidence from anatomical and experimental studies, and a perusal of that paper should show the wider basis for the view put forward by Czapek in 1897 that the phloem is to be regarded as the chief tissue concerned in the conduction of organic material in the plant. In later papers (*Annals of Botany*, 1915, 1917) I dealt with many of the points which call for consideration in any investigation of this problem, and indicated the nature of results obtained by the application of Senft's method of locating sugars by the formation of their osazones. Unfortunately, the war and the heavy pressure of departmental duties have held up the work, and it has not yet been possible to publish results in detail.

The following comments may be made, however, in connection with the view put forward by Prof. Dixon and his collaborator. The sugars are described as having to traverse the cross-partitions (of phloem cells) as a stream if they use this tissue as a conduit. It may be doubted whether the movement can be compared to the mass movement of water in a tube, and other considerations have been urged in the later paper referred to above.

Experiments made by Czapek (referred to in my last paper, pp. 293, 294, 303) showed that removal of starch from an attached leaf continued if a short length of the petiole was plasmolysed (but not killed), that a killed (boiled) portion of petiole prevented translocation permanently, but that a narcotised portion only temporarily interrupted the process, which was renewed on recovery of the tissues. Though perhaps not altogether excluding the possibility of conduction in the wood, such experiments appear to point to the activity of living cells in the transportation, and I have suggested a possible explanation of the continuance of the process in plasmolysed (living) cells, assuming the sieve-tubes to be the channels concerned (*loc. cit.*, p. 303).

Various histological features of sieve-tubes and their associated cells appear to harmonise well with the view that they serve to conduct carbohydrates, *e.g.* their continuity, distribution, and degree of development in different types of plants, the structure of the sieve-plate, the distribution of connecting-

threads, the relation of sieve-tubes in the parasite Cuscuta to those of its host, etc.

A particularly interesting piece of evidence in favour of the phloem view is to be found in a paper by Schneider-Orelli on a leaf miner of the apple (*Centralb. f. Bakt.*, 11 Abt., 1909, 24, p. 158; cited by Schroeder, *Zeitschr. f. Bot.*, 1911, pp. 770-71). Where the caterpillar had bored through strong veins the destruction of the tissue affected the storage of starch in the leaf. It was found that the destruction of the xylem and the greater part of the bundle sheath could be brought about without causing an accumulation of starch in the distal part of the leaf (by interrupting the conducting channels), but that injury to the phloem resulted in an accumulation of starch proportional to the extent of the injury. Similarly, it has been found by Quanjer and others that the phloem necrosis associated with the leaf-curl of potatoes interferes with the transport of starch from the leaf, with the result that the tubers fail to develop properly.

It may also be noted that in a paper on the biology of a species of Aphis, Davidson (*Annals of Applied Biology*, v. 1921, p. 60) states that the phloem of the vascular bundles is especially sought for by these insects when tapping the plant for nutriment, and that this point is undergoing further investigation.

Although the case of Lepidodendron undoubtedly presents difficulties (a possible solution was suggested by me, *loc. cit.*, pp. 307-9), the difficulties are scarcely less on Prof. Dixon's view in the case of various aquatic plants which normally produce no xylem or only discontinuous traces.

I look forward with very great interest to the results of the work which Prof. Dixon and Mr. Ball have in hand, as the problem is a long-standing one. An urgent need is for more data on which to elaborate a theory of translocation in general.

Pricked Letters and Ultimate Ratios.

IT is the purpose of this note to point out an earlier use of "pricked letters" to denote infinitesimals and of the phrase "prime and ultimate ratios" than is recorded in our histories of mathematics.

It will be recalled to mind that as early as 1665 Isaac Newton used "pricked letters" to denote fluxions or velocities. He did not permit his notation to appear in print before 1693. Between 1693 and 1704 the dot came to be used by other English writers, but nearly all of them departed from Newton in interpreting $\dot{x}$ to mean, not a velocity, but an infinitely small quantity or increment, like the Leibnizian *dx*.

Recently the present writer has noticed that as early as 1668 Nicholas Mercator used the dot to mark an infinitesimal, in an article in the Philosophical Transactions,[1] which contains illustrations of his "Logarithmotechnia" of 1668. Mercator uses in his article the letter I with a dot over it to indicate an infinitesimal difference.[2] This date, 1668, marks the earliest use of the dot for this purpose known to us. It was long before Newton allowed any part of his fluxions to appear in print and before Leibniz began to develop his calculus. Mercator could not have regarded the dot simply as part of the letter I, for (though the type is not quite clear) it appears to have been the capital letter. Moreover, in computing logarithms he writes the dot over a number ($\dot{64}$, for example), to serve as a reminder that 64 is the coefficient of a power of an infinitesimal.

In the same article Mercator used a terminology[3] resembling the famous phrase "prime and ultimate ratios," used by Newton in his "Principia," 1687 (Bk. i. Sec. i. Lem. xi., Scholium). Mercator writes "ratiunculae" or little ratios, while Newton uses "rationes" or ratios. Mercator says "primae et ultimae ratiuncularum," Newton speaks of "rationes primae," and "rationes ultimae." We observe also that in 1695 Edmund Halley (Phil. Trans.) used "ratiuncula," and that in 1706 William Jones ("Synopsis Palmariorum," p. 174) made the statement: "Let $\dot{x}$ be a Ratiuncula or Fluxion of the ratio 1 to 1 + x."

It appears on the surface as if there had been a giving and receiving. In his letter to Oldenburg, dated October 24, 1676, Newton mentions Mercator's "Logarithmotechnia," but he nowhere refers to Mercator's illustrative article from which we have quoted. That article is of minor importance. It is not reproduced in the abridged edition of the Philosophical Transactions, and is not mentioned in the biographical sketches of Nicholas Mercator that we have seen. Whether in private Newton had used the phrases "prime ratios" and "ultimate ratios" on or before 1668 we have no means of knowing. He first used them in print in 1687. For some years after 1660 Mercator lived in London, where he became a member of the Royal Society. Newton became a member in 1672. As Newton lived at Cambridge (except during the Plague, when he was in the country), the chances that Mercator received information of Newton's work through private channels are reduced. After 1669 both Mercator's "Logarithmotechnia" and his illustrative article were in print. It is therefore possible that Newton may have adopted the phrase "prime and ultimate ratios" from Mercator. Newton's dot-symbol antedates Mercator's.

[1] Phil. Trans., London, vol. 3, p. 759 ff. Reprinted in Maseres, *Scriptores Logarithmici*, vol. 1, p. 231.

[2] The passage in question relates to the use of the infinite series for finding log ($1 \pm \dot{I}$) and is as follows: "Quare posito maximo termino = 1, et parte infinitissima (sic) differentiae = I, et mensura rationis minimae itidem $\dot{I}$." He gives proportions like the following:

$$\text{“}1 - \dot{I} \,.\, 1 :: \dot{I} \,.\, \dot{I} + \dot{I}\dot{I} + \dot{I}^3 + \dot{I}^4, \text{ etc.”}$$

Here the fourth term of the proportion is an infinite series; ratio is indicated by (.) placed at the lower edge of the line.

[3] The passage in Mercator is, " . . . non nisi semisse primae et ultimae ratiuncularum a prioribus terminis contentarum, id est, ratiuncula minori, quam quae ullis numeris exprimi possit."

Einstein's Aberration Experiment.

IN the *Sitzungsberichte* of the Berlin Academy of December 8 last, which has recently come to hand,

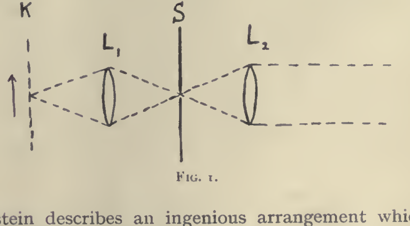

FIG. 1.

Einstein describes an ingenious arrangement which he suggests might serve to decide between the

classical theory of light and the theory in which light is regarded as made up of single quanta of energy emitted discontinuously from luminous atoms. Fig. 1 (reproduced from the paper) illustrates the proposed experiment. K is a stream of canal rays, L_1 is a focussing lens, S is a screen containing a slit which serves to isolate a definite pencil of light, and the lens L_2 renders the emergent beam parallel. The emergent pencil is observed through a telescope focussed for infinity, so that the image of the slit in the screen S would be seen sharply focussed in the field of view. Since the atoms in the canal rays emitting light are in motion, the Doppler effect comes into evidence, and the rays proceeding at any instant from individual luminous atoms in different directions should, according to the wave-theory of light, be of different frequencies. Einstein suggests that the rays passing through the slit S and incident on the upper and lower parts of the lens L_2 should consequently be of different frequencies. If, therefore, a layer of a dispersing medium such as carbon disulphide be placed between the lens L_2 and the observing telescope, the different rays would travel through it with different velocities. Hence the wave-front should suffer an aberration and the image of the slit seen in the focal plane should shift through an extent proportionate to the thickness of the dispersing layer introduced. Einstein conceives that according to the quantum theory of light, on the other hand, such displacement should not occur, and he believes that the proposed arrangement furnishes an *experimentum crucis* to decide between the rival theories.

I wish here to direct attention to a fallacy which is present in Einstein's reasoning and invalidates it. It is clear that in the proposed experiment what would be observed are not the moving luminous atoms but the fixed edges of the illuminated slit in S, and it is easily shown that even according to the principles of the wave-theory no aberration of the image of the latter could be expected. To make this evident we may conceive the slit to be extremely narrow, or in the alternative, if it be wide, regard it as divided up into a large number of very narrow elements each of which, according to Huyghens's principle, would operate as a secondary source of light. The light from any small portion of the lens L_1 arriving at the slit would spread out by diffraction in all directions in the form of cylindrical waves, so that the waves reaching L_2 would consist everywhere of *superposed* wave-fronts of all the frequencies reaching the slit, and not, as Einstein supposes, of different frequencies at different points of L_2. The waves diverging from S would thus pass through L_2 and the dispersing medium behind it according to the ordinary laws of geometrical optics, and no shift or aberration of the image of the slit would occur. The error in Einstein's reasoning lies in his having ignored the vitally important part which diffraction plays, according to the wave-theory of light, in the theory of the formation of images of illuminated apertures by optical instruments.

The Weathering of Mortar.

MR. RICHARDSON's letter (March 9, p. 310) anent the above calls, I think, for some further remarks. My observations never led me to conclude that the growth of moss was in any way responsible for the development of the ridge-and-ring markings upon the surfaces of old and exposed mortar. I have seldom seen moss growing thereon, but lichen is very often present, covering the whole surface, and not limited to the linear concavities. There is a row of fishermen's cottages at St. Ives, Cornwall, fully exposed to the sea, and the old mortar in the walls shows the markings in unusual perfection, but there is no evidence that moss ever grew upon it.

In 1896 I suggested that the phenomenon was a physical effect due to the expansion and contraction—or perhaps the former only—set up by alternations of temperature in a substance like mortar. Strains and stresses along lines of least resistance would tend to destroy compaction along such lines, rendering them more liable to be deepened by atmospheric erosion. Possibly the expansion and contraction in the stones themselves may also affect the stability of the mortar.

FIG. 1.

The accompanying photograph (Fig. 1), taken many years ago, shows some ridge-and-ringed mortar at the base of an old wall near Corfe. The wall faced south, and was built of Purbeck limestone. During its construction some thin pieces were placed vertically between the two masses of mortar. The penny fixes the dimensions of the mural components. The structure here was very conspicuous, but, with lapse of time, the photograph has faded somewhat.

Metchnikoff (Mečnikov) and Russian Science in 1883.

I HAVE read with the greatest interest the review of the "Life of Elie Metchnikoff" published in NATURE of February 9. In NATURE of November 17, 1921, I gave an account of the present state of science in Russia and its "proletarisation," and I beg to be permitted to say a few words on the state of science under Russian absolutism.

According to the above review, the book referred to says that the government of the university of Odessa became more and more reactionary; but it was not for political reasons that Metchnikoff left the university—the reasons were "scientific."

Following an invitation, I took part in the Congress

of Naturalists which was held in Odessa in August 1883, and of which I am the only foreign survivor. I became acquainted with the most prominent professors of that University and found that they were first-rate men of science, without a trace of anything "backward and reactionary." And yet this reproach is correct, but it refers to the State director of the university. A man, unsympathetic, gloomy, reactionary, every inch a bureaucrat, and fairly old, inaugurated the first general meeting with the following severe words: "You came here to speak of science and I hope that you will speak *only* of science!" After this rose Metchnikoff and gave a brilliant account of his recent and unpublished work on phagocytosis, which was received with enthusiastic applause by the whole assembly.

I congratulated my Russian colleagues and the University upon having such a professor, but they replied with regret that he no longer belonged to the University, and upon asking for reasons I was given the explanation: Metchnikoff as a professor of zoology announced a course of lectures "On the Theory of Evolution." And now the very reverse took place of what I described four months ago (see above). The director summoned Metchnikoff to his office and said to him: "It appears that you are going to lecture on Darwinism? If it is so, then you must submit your written lectures to my censorship and I will tell you what I allow you to say to the students and what not!" Metchnikoff did not accept this explanation of the "Lehr- und Lernfreiheit," he did not submit his notes to the curator; he resigned the professorship. Russia was not the soil for such a genius, and it was good fortune for him and for science that he left for Paris and for Pasteur.

Bohuslav Brauner.

Bohemian University, Prague, March 9.

The Accuracy of Tide-predicting Machines.

Under the above title in Nature of February 23, Dr. A. T. Doodson comments on my letter that appeared in the issue of Nature for February 2 under the same title. Unfortunately, Dr. Doodson is dealing with a matter outside the scope of my letter, and his statement that he is not "convinced by the tests recorded by Mr. Marmer" in no way invalidates any of the statements in my letter.

As specifically stated in my letter, it was prompted by a desire to prevent the possible misconstruction, on the part of *those not familiar with tide-predicting machines*, of a statement to the effect that tide-predicting machines are subject to "serious errors in their results." Occasion was also taken to direct attention to the different types of tide predictors and to a table showing the differences between computed and predicted heights for one day in the case of Hong Kong.

With none of the statements relative to these matters does Dr. Doodson appear to be in disagreement. What he does question, however, is something outside the scope of my letter, namely, whether the tide predictor with the operation of which I am familiar is or is not suitable for predicting hourly heights for *research purposes* within 0·05 ft. for a spring range of 30 ft. Not being concerned with that question at the time, there appeared no occasion for the tests, "exhaustive and convincing," that Dr. Doodson desires.

In his letter Dr. Doodson states that the tide predictors at his command were found unsuitable for use in the elimination from the observed tide of the tide due to a number of constituents. Nevertheless, this does not invalidate the general proposition that in such problems "the tide predictor should very materially lessen the laborious computations involved."

H. A. Marmer.

U.S. Coast and Geodetic Survey, Washington, D.C., March 18.

It seemed to me that Mr. Marmer's first letter left the impression that the U.S.A. machine is one that is free from serious errors of the order of magnitude of those of the British machines, and I raised the question of proof. I said that I should be very glad to know that this machine could produce hourly heights to within 0·05 ft. with a spring range of 30 ft. I *questioned* whether it would or would not give errors of 0·4 ft. in such a case. If my doubts are warranted, then the U.S.A. machine also is subject to serious errors, which, as I suggested, would prohibit its use for the research work mentioned above in Mr. Marmer's last paragraph.

A. T. Doodson.

Tidal Institute, University of Liverpool, April 3, 1922.

Pythagoras's Theorem as a Repeating Pattern.

It may not be generally known that the Theorem of Pythagoras, Euclid I. 47, is closely connected with the Theory of Repeating Patterns in space of two dimensions. The simplest proof by dissection of that Theorem establishes at once that any two squares placed in contact as in the accompanying diagrams (Fig. 1) constitute a figure such that a number of them can be assembled so as completely to fill flat space.

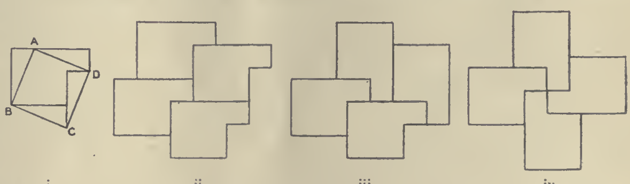

Fig. 1.

Fig. 1 (i.) shows the proof by dissection. Also the large square, regarded as a base, shows by the Principle of Transformation in the Theory of Repeating Patterns that the figure formed of the two squares is a repeating pattern. The transformation consists of cutting out the triangles the bases of which are BC and CD and erecting them upon the sides BA, AD. This nature of transformation yields an infinite number of repeating patterns of a particularly interesting kind, because of this category each member has the property that the assemblages can be carried out in three different ways, namely, so as to exhibit 1, 2, or 4 orientations or aspects of repeat respectively. In the present case of the Pythagorean Repeat the three ways of assembling are shown in Fig. 1 (ii., iii., and iv.).

The Age of the Earth.[1]

By Prof. J. Joly, F.R.S.

"THE Age of the Earth" is a somewhat ambiguous phrase. From the geological point of view it is generally understood to mean the age of the ocean: in other words the age of the earth since the beginning of those geological surface changes which are due to denudation. But another meaning may be ascribed to the term. We may assume the beginning to date from the cooling of a highly heated surface to the point of solidification. In this case we include in the age those long periods of Archæan time during which the activity of water played a subordinate part and volcanic commotion prevailed among the semi-fluid, rocky constituents of the globe. Yet a third interpretation refers the birth time to a still more remote and indefinite epoch when the world became differentiated as a planet by activities, of the nature of which we are ignorant. Astronomical deductions and speculations regarding the Age are mainly concerned with the last period.

What I have to say will be restricted, almost entirely, to the first interpretation of the term. I mean by the age of the earth the period which has elapsed since its surface became the scene of world-wide denudative forces and the foundations of organic evolution were laid.

In virtue of these denudative forces we find ourselves possessed of certain methods of estimating the Age which are valid upon the assumption that denudation proceeds in our time at a rate not greatly differing from its mean rate over geological time.

The bases of this assumption are as follows:—

(*a*) That the chief factor in denudative activity being the rain supply falling on the land, solar heat and atmospheric circulation are primary causes. The life on the globe since very early times and the narrow temperature limits conditioning protoplasmic existence and activity show that great extremes of solar radiation cannot have affected denudation for long periods in the past. Mere climatal extremes do not sensibly affect solvent denudation. Atmospheric circulation, being largely conditioned by the earth's rotation and the distribution of solar heat, cannot have varied to any effective extent.

(*b*) That a considerable percentage of the existing land area being rainless, changes in continental area cannot greatly affect the amount of denudation: the belt undergoing denudation being merely displaced outwards or inwards. The evidence derived from palæography and from the extent of sedimentary deposits in all ages shows that the present land area is not greatly different from the past mean area.

c) That the minor factors affecting solvent and detrital denudation being very many and of very different character are unlikely to combine at any time, and for any long period, in one direction, so as to create a considerable departure from the mean.

Time will not permit a discussion of these statements. I shall refer but briefly to the methods by which the statistics of solvent and detrital denudation are used to afford the age of the ocean.

(1) The chemistry of the ocean and of the rocks is the key to our position. As the result of a comparative study of the primary or igneous rocks and the secondary or sedimentary rocks we find that, say, n grams of sodium are shed into the ocean for each tonne of igneous rock converted into sedimentary rock, and in the ocean we find N grams of sodium. The total denudation over geological time has, therefore, been N/n expressed in tonnes of denuded igneous rock. Our study also tells us the average total loss attending the conversion of the primary rock into sediment, and so we get the total of the secondary rocks in tonnes. We now go to the principal rivers of the world and availing ourselves of estimates which have been made of the amounts of sediment—*i.e.* of secondary rock material—which they transport from the land in a year, we calculate the number of years which it would take to lay down in the ocean the great mass of sediment generated in the past ages. After certain allowances this comes out as about 100 million years.

(2) Again the total of oceanic sodium may give us the Age in another and more direct way. We know that by far the greater part of this sodium was carried into it by the rivers during geological time. We turn to the analyses of river water and estimate the total annual supply of this element to the ocean. Dividing the latter into the former and making certain allowances we find an Age which is about 100 million years.

(3) A third and more difficult method is independent of our knowledge of chemical denudation. We estimate the maximum thickness of the integral sedimentary deposits, and knowing the burthen of sediment conveyed per annum by the rivers, we estimate the maximum thickness of deposit annually derived from the same; we divide the latter into the former and find an age which, again, is about 100 million years.

Of these methods, that which involves the sodium modulus only is the most direct. Of course the reason for selecting this particular element as a modulus is because of its great solubility, on account of which it alone among the dissolved oceanic constituents has been preserved from organic abstraction or chemical precipitation. This method has been examined by many critics. Notably by Sollas, who, in a presidential address to the Geological Society in 1909, subjects it to searching examination. He concludes that a period of 175 millions of years may be reached upon certain assumptions, and that this must be very nearly the maximum allowable. My own examination of this method has led me to believe that it is *possible* that 150 millions of years may be indicated by it, and that 200 millions of years would not be reconcilable with our present knowledge of the factors involved. This would, as I have already stated, apply only to the duration of sedimentation. It cannot be compared with data which apply to an age dating back into the Archæan.

[1] Discourse delivered at the Royal Institution on Friday, February 24.

There was, indeed, some scanty sedimentation in Archæan times. We cannot form any estimate of its effects either upon our numerator or upon our denominator save that we seem entitled to conclude that they were small. "The Archæan was essentially a period of world-wide vulcanism, and in the relative proportions of rocks of igneous and sedimentary origin represents a departure from the uniformity of conditions of later geological time." I quote from the monograph of Van Hise and Leith.

Before passing on to the results based upon radioactivity I must refer to one point in particular which has been urged against accepting present-day rates of denudation as a basis of time measurement. It is said we live in a period of abnormal continental elevation which, it is asserted, involves excessive solvent denudation. A little attention to the nature and conditions of solvent denudation should have sufficed to forestall the argument. But a ready method of dealing with it is available. The continent of North America has a mean elevation of 700 metres: it is being denuded at the rate of 79 tonnes per square mile per annum: for South America the corresponding figures are 650 metres and 50 tonnes. Now Europe has a much lower mean elevation—300 metres. Its rate of denudation is, however, 100 tons per square mile per annum. The rate of solvent denudation is, in fact, by measurement found to be *less* for the more elevated land, as, theoretically, it should be. The argument then, if it has any basis, would indicate that the age as found from solvent denudation is excessive.

Prior to the advent of those methods for investigating the earth's age, which are based on radio-active changes in the elements, no serious objections to the results reached by the geological methods were raised, so far as I know. There were some, indeed, who regarded the age as excessive. Thus Becker arrived at a lesser figure by taking into account the progressive impoverishment of the surface materials during geological time. The validity of the correction is, however, open to doubt. Others considered that the organic changes recorded in the rocks required a longer period. Sollas gave, as I think, a clear answer to this objection in his "Age of the Earth." Both Lyell and Geikie, and Poulton, had in past years upheld the doctrine of Uniformity. But the advent of the radio-active method, as founded on the uranium family of elements, seemed to point to a vastly greater Age; leading, in fact, to the extraordinary conclusion that the present rate of solvent denudation is not less than four times and may be eight (or even more) times in excess of the average rate obtaining during the past.

The earliest suggestion of the possibility of using the stored-up products of radio-active change came from Rutherford. He, and later Strutt (now Lord Rayleigh), applied the accumulation of helium to the evaluation of geological time. Strutt laid out a geological chronology, the first of its kind, but considered he was dealing with minor limits. Boltwood used the residual product of uranium—lead—and for Archæan (?) materials reached as much as 1640 million years. As I have already said, the denudative method cannot be regarded as extending to those remote times. But such results as 430×10^6 years for Silurian or Ordovician deposits, and 1200×10^6 years for Post-Jatulian are quite out of harmony with the denudative method. To-day the matter stands thus:—A number of results are available based upon the use of carefully selected material, and when the material is thus selected the ratio of lead to uranium —the "lead ratio" as it is termed—increases as we go downwards and diminishes as we go upwards in the strata, preserving a fair degree of agreement even for widely separated localities.

Those who would rest content with this result, however, can do so only by ignoring the very interesting and suggestive fact that when we base the results on the lead ratio of selected thorium minerals, we arrive at ages which are in substantial agreement with the results reached by the denudative method. On the face of it this agreement gives strong support to the conclusions reached by methods absolutely different in nature.

For long it was known that thorium minerals—such as thorite—gave persistently lower ages than uranium minerals. It became the custom with some to treat these ages as untrustworthy. But we know now that this attitude is not justified, but rather that the onus of explaining away the impressive agreement between the indications of thorium lead and denudative statistics rests with those who would reject the Age supported by both.

Soddy's determination of the atomic weight of the thorium lead isotope, in 1917, afforded material for an age determination on a very large scale, and from the nature of the research, one of special value. The material was a thorite from Ceylon; from rocks immediately overlying the Charnockite series. The latter is extremely ancient—Lewisian or Lower Archæan. Upon reading in Nature Prof. Soddy's account of his determination of the atomic weight of the lead derived from these rocks, I estimated that the quantity of lead extracted from the thorite gave an age of 130 millions of years for the time since this mineral had been generated; and on communicating with Prof. Soddy I found that he had reached a somewhat similar conclusion.

At this time, however, there was the possibility that thorium lead was not altogether stable. Suspicion fell more especially on thallium as the final product. Two experimental results, however, laid this doubt to rest: experiments upon a thorianite made in my laboratory by J. R. Cotter failed to detect even spectroscopic traces of this element, and there was insufficient thallium found in the thorite dealt with by Prof. Soddy. In a subsequent letter to Nature Prof. Soddy states that a research carried out at the Radium Institute of Vienna supported the view that the lead isotopes derived from thorium were both stable. I shall refer presently to yet additional evidence that the transformations of the thorium family cease with lead.

Writing to Nature in support of the hypothesis then under discussion—*i.e.* that thorium lead was unstable—A. Holmes cited a result on a selected specimen of uraninite, showing that the rocks in which Soddy's thorite occurred were, according to the uranium-lead ratio, 512 millions of years old. Previous uranium-lead ratios had assigned a much greater age

to them. Here, then, the results join issue: the uranium result is just four times as great as the thorium. We notice, too, that on the uranium-scale of time this thorite must be older than Silurian or Ordovician, which have been determined by uranium lead as 430 millions of years ago. Probably its age dates back to Cambrian or even to pre-Cambrian time. From what we have already inferred we cannot regard 130 millions of years for early Palæozoic time as irreconcilable with the maxima which denudative methods afford. More recently, lead derived from a Norwegian thorite of Langesundfiord—also of lower Palæozoic age—seems to reveal an age of 150 millions of years. In this case, also, there is the added security of a determination of the atomic weight of the lead.

We cannot discredit these results on the score of radio-active instability of the lead. Why, then, set them aside in favour of results reached on uranium lead, which are in hopeless contradiction with the indications of the record of the surface activities of the globe? It is, indeed, not too much to say that the whole position is now reversed and that to-day suspicion attaches to the uranium-lead ratio. And, as we shall see, there is much unknown about the earlier radio-active sequence in the uranium series; while the discovery of isotopes opens the way to possibilities unthought of in the earlier days of radio-active science.

I shall, however, now turn to the evidence of the pleochroic halo on this matter.

The halo affords a means of investigating certain facts respecting the break-up of the radio-active elements in the remote past. For the dimensions of the halo—minute though they be—can be determined with considerable accuracy, and these dimensions are conditioned by the added effects of the several α-rays emitted by the transmuting elements. Bragg and Kleeman observed and measured just such integral ionisation effects in air. In the rocks the ionisation curves, owing to the great stopping power of minerals, are on a scale 2000 times as small. They are very faithful hieroglyphics, however, and carry back our knowledge over an appalling vista of time.

One single α-ray produces a well-known curve of ionisation determined by Geiger. The range of the ray does not affect the general nature of the curve. If we imagine uranium or thorium as parent elements contained in a minute crystal—of zircon, for instance—we must picture the various α-rays affecting the surrounding substance—mica, we may suppose—in such a way as to build up concentric spherical shells more or less overlapping and corresponding to the radial distances at which the ionisation of the several rays is at a maximum. As seen in section upon cleaved flakes of the mica, we find concentric coloured rings representing the ionisation due to the rays.

In order to arrive at the theoretical location of these rings we must add up the several ionisation effects as observed in air. This involves assigning a Geiger curve to each ray according to its range and adding up the ordinates.

Let us consider first the case of the thorium halo. Fig. 1 is a curve arrived at in the manner I have just described. Its ordinates are proportional to the integral ionisation effects of those radio-active elements in the thorium series which emit α-rays. And above it I have marked, calculated into the range in air, the positions of the coloured rings which in biotite we observe encircling a minute mineral particle containing thorium and all the successive products of its transmutation. This, of course, necessitates magnifying the halo enormously—rather more than 2000 diameters. You perceive that the halo very faithfully conforms to the features of the air-curve. It may be of interest to mention that the finding of the third ring led to the discovery of the prominence on the curve which accounts for it. This part of the curve had originally been plotted from an insufficient number of ordinates. This close agreement really reveals a very important fact. The air-curve depends for its dimensions on the ranges of the several α-rays as we measure them to-day in the laboratory. The halo-measurements refer to radio-active effects which began their record in this mica in Carboniferous times—possibly long before. The halo reveals no sign of change in the several ranges concerned. As you are aware, the rate of break up, the transformation constant of the element, is related to the range. We are, therefore, in the case of the thorium family, entitled to read in these minute and ancient records a guarantee that the accumulation of the final product—the thorium isotopes of lead—was in the remote past effected at just such a rate as we have inferred from the splendid researches of our day. The thorium halo gives us this guarantee. It also tells us that it is improbable that the resulting lead is unstable. For if it were we must find room for rays additional to those we have used in deriving the ionisation curve. True, a coincidence of range might enable a ray to lie concealed in the halo; but the fit of the halo is so absolutely faithful to every feature of the curve that this seems improbable.

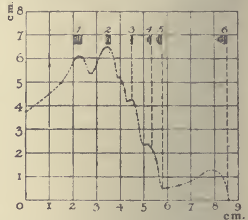

FIG. 1.

It is also possible to observe the successive stages of development in thorium haloes. The first rings to appear are those corresponding to the two conspicuous crests of the curve, Fig. 1. If the central nucleus is small or feeble, nothing more may be developed.

We now turn to the uranium curve. The eight contributory ionisation curves are placed according to the range of each ray, and Fig. 2 shows the curve produced by adding up the ordinates. Above it are laid out the several rings observed in the uranium halo.

Looking at these rings, we notice that the outer features of the halo seem in fair agreement with the present-day ranges. But the innermost ring has a larger radius than would be expected from the curve. Much care has been expended in verifying this point. In the Devonian mica of County Carlow these haloes are found in every stage of development according to the size or activity of the nucleus. The uranium halo

begins as a single delicate ring surrounding the minute central nucleus. It can be measured from a stage bordering on invisibility to a stage when its central area is beginning to darken up and the first shadowy signs of the outermost ring of all—that due solely to radium C—appear. A large number of readings on these embryonic haloes, made recently by various observers, confirm the mean value of is radius as cited in a paper communicated to the Royal Society in 1916. The discrepancy with the theoretic curve is small; 10 or 12 pei cent. of the external radius. The allowance for, and measurement of, the nucleus is sufficiently difficult to introduce some uncertainty.

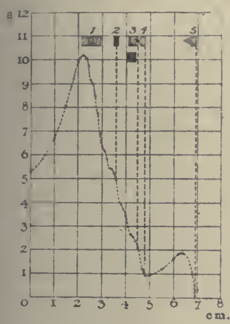

Fig. 2.

This misfit may be of considerable significance. I have already reminded you that the range of the α-ray emitted by a transforming element is related to its rate of break-up. The range is longer for the shorter lived elements. Now here the first ring of the uranium halo in mica shows a longer range than we would expect from the air-curve as observed to-day. The agreement between the two in other cases appears to show that this is not due to any unknown effect influencing the retardation in mica. The location of the first uranium ring is mainly referable to those short-range α-rays arising from the initial transformations of the uranium series. We infer that one or more of these rays must have had a longer range in past times and, of course, that the corresponding transformation periods must have been shorter. A specially influential ray is that slowest of all the rays—that which is emitted in the break-up of uranium 1. The discrepancy might be due to this ray possessing a greater range in early geological times. But, whatever the cause, the nature of the misfit suggests evidently that formerly the rate of transformation of uranium to lead was faster than it is to-day.

It is with some reserve that I refer here to measurements made lately on haloes of comparatively recent and of very remote geological ages. I say "with reserve," for not only are the results of a nature calling for very adequate confirmation, but the measurements present considerable difficulty. The point at issue may be stated in a few words:—Is the abnormality observed in the dimensions of the uranium halo dependent in amount upon the antiquity of the rock in which the halo is developed?

I had sought occasionally for uranium haloes in rocks younger than the Leinster granite—which is of early Devonian age. The granite of Mourne, which is of Eocene or early Tertiary age, for long refused to reveal any haloes suitable for measurement. However, recently, I was so fortunate as to find a few of these early halo rings which I was able to measure. Further search has revealed a few more; but htey are excessively scarce and rather difficult to detect. The nuclei of these haloes are only rarely zircon—they seem to be apatite—possibly allanite—and their average size is greater than the zircon nuclei of the Carlow mica. Both the mineral nature of the Mourne nuclei and their dimensions involve, therefore, a bigger subtractive correction on the observed radius than is required in the case of the Carlow haloes. But in addition to this, there appears to be a small difference in the external radius of the Eocene halo and that of the Devonian halo. According to a large number of readings by several observers, some of whom were not acquainted with the question at issue, the external radius of the Eocene halo-ring—no allowance being made for the nuclear radius—is 0·0135 mm. The same observers obtained for the Devonian halo 0·0146 mm.—without allowance for the nucleus. The nuclear correction, as I have said, would have increased the discrepancy, but the correction is a difficult one. There is no reason to believe that *more* than 1 per cent. of this difference can be ascribed to the chemical composition or density of the micas, both of which have been investigated.

Still more recently I have found these primary ring-haloes in the micas of Arendal and Yitterby, which are said to be of Archæan age, and which are certainly extremely ancient. These haloes appear to possess a radial dimension of 0·0160 mms., or a little less. Here, again, the nature of the mica does not appear to be responsible. According to these measurements it would appear that the radius of the Eocene halo-ring must be increased by about 7 per cent. to attain the size of the Devonian halo-ring, and that this is, in radial dimension, about 10 per cent. smaller than the Archean. It would seem as if we might determine a geological chronology on the dimensions of these halo-rings!

The foregoing results, if confirmed, would give strong support to the view that some factor, variable over geological time, had affected the ranges and periods of certain elements concerned in building up the uranium halo. However, too much stress must not be placed on these measurements till they are confirmed by haloes in yet other micas. Pending further investigations, I return to the fact that the uranium halo of Devonian age does not conform to the ionisation curve of the uranium family as determined on present-day measurements. Serious discrepancy seems confined to the shorter ranges, more especially with that primary range which is most influential in determining the rate of production of uranium lead.

We do not appear to be in a position to deny the possibility that uranium 1 may have slowed down in its rate of decay over geological time. Such laboratory observations as can be extended to the case of short-lived elements would not, probably, shed any light on the matter. It is a possibility long ago suggested by Rutherford. But if this is the explanation we must admit that in the case of thorium any corresponding effect must have been much smaller. On the whole the former influence of one or more isotopes of uranium—which possibly may almost have disappeared—seems the more probable explanation. Hypothetical isotopes of uranium have been invoked by highly competent authorities to meet the difficulties affecting the ionisation accounts of the uranium family of elements. Boltwood suggests as "not impossible"

that what we now call uranium consists of three radio-elements; a parent element and two isotopic products all emitting α-rays (*Phil. Mag.*, July 1920). In 1917, A. Riccard put forward the view that the parent of actinium is a third isotope of uranium not belonging to the uranium family and having an atomic weight of 240. This view is regarded favourably by Soddy and Cranston. It clears up the difficulty respecting the atomic weight of uranium and fits in with the atomic weights of radium and of uranium lead. Soddy and Cranston remark that in order to explain, in this case, the constant ratio of actinium to uranium observed in minerals we must suppose the period of uranium 1 and of the hypothetical isotope to be the same. This difficulty, however, is removed if we may assume that the ratio varied over geological time.

A somewhat similar theory to Riccard's may be invoked to explain the abnormality of the Devonian uranium halo. We have these facts to go on:—The age indicated by uranium for Lower or Pre-Palæozoic rocks is about 4 times too great as compared with the age indicated by thorium. We assume, therefore, that three-fourths of the lead as measured in uranium minerals is derived from a certain isotope. This isotope, not having been detected in our time by its primary α-radiation, we must suppose to be now sensibly exhausted. We, therefore, have a known mass of this isotope transforming to lead in a known time—130×10^6 years. Assuming that only 1 per cent. of it is left we get its transformation constant ($3 \cdot 5 \times 10^{-8}$), and by Geiger and Nutall's relation we find the corresponding range as 2·6 cms. at 0° C.; or about 2·75 cms. at 15° C. To-day the α-radiation of the hypothetical body would be only $\frac{1}{1000}$ of that due to uranium 1, but during the period since the Devonian there will be about 3 α-rays from the short-lived isotope to 1 from the long-lived. The integral curve of ionisation as modified by these hypothetical results would be in agreement with the Devonian halo. We have to assume that the ranges of the rays emitted by the successive disintegrating products of the supposed isotope were such as to leave the outer features of the halo sensibly undisturbed. This seems not improbable.

The salient facts which appear in the study of radio-active haloes are:—firstly, that the agreement of our laboratory measurements of to-day with the features of the Palæozoic thorium halo is such as to support the view that the periods of the several elements concerned in its genesis have remained unchanged over 130 millions of years. This fact, taken along with the stability of thorium lead, seems to render its reading of geological time authentic in a high degree. Its indications are confirmed by the consistent testimony of the denudative processes which have progressed on the earth's surface. Secondly, it appears that the uranium halo is not in conformity with the period we ascribe to-day to uranium; a disagreement which is emphasised by the failure of uranium-time to conform with the united testimony of thorium-time and denudative-time; as well as by much that remains unexplained respecting the earlier changes in the uranium family of elements.

The complete tale is not yet told, but I think the balance of probability is in favour of an age between 150 and 200 millions of years for the earliest advent of geological conditions upon the globe.

Astronomical investigation on the subject of the age of the earth deals, generally, with that greater age which must be ascribed to the earth as a planet. For this age vast periods have been claimed. But it is possible to reconcile superior ages for the earth as a planet with comparatively brief geological time. And—to my mind—in doing so we proceed upon what is no more than a necessary deduction based on our knowledge of the radio-activity of terrestrial materials. I would go further—still, as I believe, logically,—and ascribe to radio-active energy an influence on planetary and stellar evolution much greater than has hitherto been admitted.

The only planet we can investigate at all closely is, of course, our earth. And what do we find? In its surface materials there are sufficient of the radio-active elements, as Lord Rayleigh first showed, to account for the observed average temperature gradient if the surface conditions extend a little way, about 19 kilometres, inwards. It is, for many reasons, in the highest degree improbable that such a definitely defined radio-active layer exists. Nor is it probable that the earth's interior is free from radio-active substances. We find both uranium and thorium in meteorites containing a large percentage of iron and nickel, and, although they have not as yet been found in meteoric iron, we know from the mean density of the earth that its interior cannot be composed of pure iron. It is probable that a considerable proportion (some 40 per cent.) of siliceous materials are intermingled: and when such exists in meteorites invariably we find the radio-active elements. By what conceivable activity was all the uranium and thorium separated out and brought to the surface?

The view that radio-active elements exist in the earth's interior is sometimes met by a formal denial that the earth can be getting hotter within. Upon what evidence is this denial based? If the central core of the earth for a radial distance of 2000 kilometres—say—had risen in temperature by 1000° C. over geological time—and upon a low assumption of the interior radio-activity it might reach this temperature in 150 million years—would we be aware of the fact? Would the day be appreciably lengthened? Would there be any effect at all if the outer parts were cooling due to loss of primal heat? We have further to consider that only over the short period of historical time would any observations be available. The denial is quite baseless so far as my estimates go.

Well, then, if our earth is heating up within, is there not an impending termination to our geological age? Kelvin showed how complete is the thermal isolation of the earth's interior, and it is certain that interior heat is not now escaping. The rise of temperature within must go on till the present epoch succumbs to the accumulated energy. Then must ensue a period of vulcanicity which will end life upon the globe, and probably reverse the chemical work stored up by ages of denudative and organic activity. The whole sequence of events — rapid cooling by radiation, restoration of the oceans and, possibly, re-birth of life and of its evolutionary history—would begin all over again. On this view the Age we have been studying

may be one of many and will inevitably attain its three score and ten; terminating in labour and sorrow. But there must come a rejuvenation, and the rejuvenation, possibly, may one day be pondered by other Minds than ours. Remember that after some ten thousand millions of years there still survives 50 per cent. of the heat-generating elements, and the effect of their diminution is only to lengthen out the recurring geological ages. Our planetary companions may be in various stages of such cyclical changes.

Recovery of Hughes's Original Microphones and Other Instruments of Historic Interest.

By A. A. CAMPBELL SWINTON, F.R.S.

FROM the perusal of David Hughes's note-books recently bequeathed to the British Museum by Mrs. Hughes, and sent to me for examination by the Keeper of the Manuscripts (see NATURE, March 9, 1922, pp. 315-316), it became obvious to me that Hughes must at one time have possessed numerous original instruments, mostly constructed with his own hands. Having been informed that the note-books had been rescued from "an incredible accumulation of useless lumber," it occurred to me to try to locate this "lumber" if still existent, and to see whether it comprised any of the instruments. To make a long story short, a room in a furniture depository not far from the Tottenham Court Road was found to be filled with Hughes's personal effects, which had been stored there since his death in 1900, when Mrs. Hughes returned to America. Having interested Col. H. G. Lyons, F.R.S., Director of the Science Museum, in the matter, the effects were carefully examined, when not only were there discovered eight more note-books—one containing an illustrated account of Hughes's invention of the microphone—but also numerous instruments.

These comprise a number of microphones, of which several are different-sized instruments of the well-known pivoted-lever type. Others consist of pointed carbon pencils, loosely held at their ends between fixed carbon sockets, the whole being mounted on sounding-boards, which in one case takes the form of an inverted Japanese ash-tray. Several more consist of carbon pencils suspended pendulum-wise by paper strips, so as to bridge other carbon pencils mounted on vertical sounding-boards, while others, again, consist of glass tubes containing either carbon blocks held together by a light spiral spring, or carbon granules. Finally, among the microphones, there is the one consisting of three French nails that has served to illustrate many a text-book.

In addition, there is an induction balance, probably the first one that Hughes made, together with the actual instruments with which he practised wireless telegraphy in 1879. They are all readily identified from the illustrated descriptions in the note-books, and include the clockwork with which currents from a single-cell battery, connected to one of the coils of the induction balance, were interrupted so as to transmit wireless signals. There are also two Bell telephones, evidently made by Hughes himself, together with two more which he says were made for him by Sax, which he used for wireless reception in connection with a water-tight pocket battery, and a special microphone that seems to have acted as a self-decohering coherer. This latter is contained in a glass bottle, the loose contact being made between a steel needle and a wire loop, which latter Hughes says he made more sensitive by coating it with soot from the flame of a spirit lamp.

With these simple pieces of home-made apparatus Hughes not only prepared the way for the modern telephone transmitter, but also transmitted and received wireless signals over distances up to 300 yards no less than 43 years ago.

All these instruments have been made over to the Science Museum, South Kensington, by Mrs. Hughes's trustees, and are now on view in Room No. 10.

Obituary.

WE learn from the *British Medical Journal* that Dr. Harris Graham died at Beirut, Syria, on February 27. Dr. Graham, who was in his sixtieth year, was of Canadian birth and was educated at Toronto and Michigan Universities. Going to Turkey as a missionary he served four years at Aintab Medical College. On its closure, he was called to Beirut and joined the American University there in 1889. During various leaves of absence he worked in Berlin and Vienna, and advanced evidence that a Culex mosquito is the carrier of dengue fever. He had an extensive practice and spoke all the principal languages of the Levant. Dr. Graham will be much missed, for he was an energetic and inspiring teacher and a physician of great acumen.

THE *Chemiker Zeitung* of March 25 announces the death, at the age of eighty-four years, of Prof. A. Naumann. Prof. Naumann was one of the first workers in the field of what is now called physical chemistry. His researches on dissociation, thermo-chemistry, and mass action, and his text-book had great influence on the science; his name is prominent in all the earlier work in this field.

THE death is announced, at the age of fifty-one years, of Dr. George Vincent Wendell, who had occupied a chair of physics at Columbia University since 1910. From 1892 to 1907 he held various posts at the Massachusetts Institute of Technology, and from 1907 to 1910 he was professor of physics and head of the department at the Stevens Institute of Technology, New Jersey.

WE deeply regret to record the death on April 9, at seventy-seven years of age, of Sir Patrick Manson, G.C.M.G., F.R.S., whose pioneer work on tropical diseases opened up fields of research of profound significance both to science and civilisation.

Current Topics and Events.

The centenary of the birth of Pasteur occurs this year, and the University and town of Strassburg, the scene of so much of Pasteur's early work, propose to celebrate the event by organising an exhibition of hygiene and bacteriology from May to October 1923, and by setting up a statue of Pasteur before the University. The exhibition will be designed to illustrate the advances in science made as a result of Pasteur's discoveries, and a congress for the discussion of questions relating to the prevention of disease will also take place. In this country a committee, consisting of Sir Charles Sherrington (chairman), Mr. A. Chaston Chapman (treasurer), Mr. H. E. Field, Prof. P. F. Franklin, Sir John M'Fadyean, Prof. C. J. Martin, Sir W. J. Pope, Sir James Walker, and Sir Almroth Wright, has been formed to forward the project and an appeal for support has been issued. Contributions to the memorial fund, which will be closed at the end of June, should be sent to Mr. Chaston Chapman, The Institute of Chemistry, 30 Russell Square, W.C.1, or to the general secretary and treasurer of the fund, M. T. Hering, 6 rue des Veaux, Strassburg. Prof. Borrel, 3 rue Koeberlé, Strassburg, is in charge of the arrangements for the exhibition and would be glad to hear from British firms who are interested. The Académie de Médecine has decided to celebrate the centenary on December 26 next, but representatives of the academy will be present at the celebrations to be held at the Institut Pasteur on December 27 next and at Strassburg on June 1 of next year.

The centenary of the birth of Gregor Mendel is to be celebrated in Brünn (Czecho-Slovakia) on September 22-24 of this year, and subsequently, on September 25-27, a congress of geneticists is to be held in Vienna. The circular of invitation recalls the erection of a statue to Mendel there in 1910. Since that date the significance of his discovery and the extraordinary importance of his work in its bearing on the fundamental conceptions of biology and the practice of breeding have been so widely recognised that international support on the present occasion is confidently invited. Those who are disposed to take part are asked to communicate with Dr. H. Iltis, Bäckergasse 10, Brünn.

We have received from the authorities a preliminary circular announcing the celebration this spring of the seventh centenary of the University of Padua, one of the oldest and most famous of the Italian universities, immortalised by Galileo and his successors. In connection with the celebrations a very interesting historical account of the University is published in the February number of *L'Emporium*, the leading art journal of Italy, showing the bearing of the University upon education in the Italy of past centuries, and the vicissitudes through which the institution passed down the ages. In spite of its associations with the great names of the past, Padua is a very modern university in so far as concerns present-day needs, ample proof of this being the large and well-equipped school of electrotechnics.

Since the School of Hygiene and Public Health of Johns Hopkins University, Baltimore, was opened in 1918, the Rockefeller Foundation has furnished funds for its maintenance from year to year. Now the Foundation has presented a sum of 1,200,000*l.*, and the trustees of the University are to assume full responsibility for the future needs of the School. In this new type of institution emphasis is laid upon the development of preventive medicine and the training of health officers. Instruction is provided in bacteriology and immunology, sanitary engineering, chemical and physiological hygiene, medical zoology, epidemiology, vital statistics and public health administration, and the regular courses of study lead to the degrees of doctor of public health and doctor and bachelor of science in hygiene. The present gift, in addition to providing endowment, will make possible the erection of the new building for the School on a site adjacent to the Johns Hopkins Medical School and Hospital.

Prof. A. Wolf, of the University of London, delivered a lecture on the Humanism of Spinoza at a special session of the Spinoza Society held at the Hague on Tuesday, March 28. The Spinoza Society ("Societas Spinozana") is the offspring of an older society founded more than forty years ago when the Spinoza monument was erected in the Hague as an international tribute to the great philosopher. Among the leading spirits of both societies are Sir Frederick Pollock, of London, Prof. L. Brunschvieg, of Paris, Prof. H. Hoeffding, of Copenhagen, Dr. C. Gebhardt, of Frankfurt, Dr. W. Meyer and Mr. H. G. van der Tak, of the Hague. The Spinoza Society has now in the press the first number of an Annual to be called "Chronicon Spinozanum," to which all the above-mentioned Spinoza scholars and others have contributed important essays. The promoters of the new society and its annual are prompted by the feeling that a wider knowledge of the philosophy and personality of Spinoza may be of special help in these difficult times, and they hope that the society may become a rallying point for those thinkers who still share Spinoza's faith in the ultimate unity and rationality of mankind.

In appointing an advisory Committee in Seismology, the Carnegie Institution of Washington has taken an important step in the promotion of the study of earthquakes in the United States. The preliminary report of the committee recognises that, as compared with England, Germany or Japan, the country has not yet taken a sufficiently active part in seismological research. At the same time, in the State of California, it possesses almost unexampled opportunities for the study of crustal movements, while several public

bodies are prepared to co-operate in such a study. The committee make several useful suggestions. Detailed surveys, it is urged, should be made of the San Andreas rift and other Californian faults. The Coast and Geodetic Survey should be invited to undertake a system of primary triangulation and precise levels in the regions most subject to movement, and to connect them with an appropriate zone of no movement east of the mountains, and also to erect new lines of columns at right angles to the San Andreas and San Jacinto faults, a time like the present being more suitable for the measurement of crustal drift than the months immediately following a great earthquake, such as that of 1906. Southern California, especially, is a region of intricate faulting, in which many of the faults are still active, and it is also one in which no primary triangulation has yet been made. The committee also indicates the value of gravity observations in connexion with the measurement of displacements along the great faults.

Sir Arthur Newsholme delivered a course of three Chadwick lectures at Birmingham on March 27-29. The subject of the first lecture was "Values in Preventive Medicine historically considered: General and Specific Sanitation." The lecturer dealt with the value of various measures against disease in their historical development. He deprecated strongly the undiscriminating call for retrenchment in public health expenditure, though urging a careful survey of the cost of all measures in vogue. The epidemiology of typhoid fever, cholera, typhus fever, and others was considered, and the lessons taught by the methods of control were surveyed. In the second lecture on "Current Values in Preventive Medicine: Relation between Prevention and Treatment," Sir Arthur Newsholme reviewed the possibilities of preventing the chief infectious diseases. The acute notifiable diseases cause only 3·1 per cent. of the total mortality, though the greater part of administrative care is devoted to them. In childhood more than half the deaths are due to infections, and in a large measure adult health is determined by disease or absence of disease in childhood. The chief object of preventive medicine is to postpone death, and this would be greatly aided if every adult submitted himself to periodical medical examination. In the third lecture, methods of evaluating public health activities were considered. Empiricism in analysis of social conditions was deprecated, as, for instance, in statements on malnutrition of school children, without further attempt to ascertain the cause. The amount spent on public health in large English and American towns averaged 5*s.* per head per annum, or, in England, from 4 to 8 per cent. of the total rates collected per head. The importance of minimum standards was emphasised, each town to receive a government grant only when it fulfilled certain minimum conditions. The lecturer concluded that the greatest return in health for money expended—apart from the ordinary sanitation of a city—was to be had in respect of maternity and child welfare, and on the prevention and treatment of tuberculosis and venereal diseases.

The *Times* reports the opening on April 5 of a lock and weir at Blanchetown, South Australia, the first of a series of such structures which will ultimately number 26, and directs attention to the very important scheme of navigation and irrigation, of which they form part, entered upon by the States of New South Wales, Victoria, and South Australia, with the sanction of the Federal Government. The rivers Murray and Murrumbidgee are to be regulated by a lockage system which will make it possible to navigate their waters for a distance of 1066 miles above the mouth of the former, and at the same time will increase greatly the area of irrigable land. Of the total number of locks, nine will be constructed by the New South Wales Government on the Murrumbidgee, eight by the Victorian Government on the Murray, and nine by the South Australian Government on the same river. The Blanchetown lock, which has been named after Mr. W. R. Randell, one of the pioneer navigators of the river, is situated 170 miles from the sea, and marks the limit of free deep water, for which reason it was chosen as the initial feature of the undertaking. The work, which was begun seven years ago, has been much impeded by floods and industrial troubles, so that the lock was only completed in September last.

Lectures at the Royal Institution after Easter will be resumed on Tuesday, April 25, when Sir Arthur Keith will begin a course of three further lectures on "Anthropological Problems of the British Empire," Series II.: "Racial Problems of Africa." The Tyndall Lectures will be delivered this year by Prof. W. Bulloch on "Tyndall's Biological Researches and the Foundations of Bacteriology," and Sir Percy Sykes will give two lectures on Persia. On Thursday afternoons there will be two lectures by Prof. E. H. Barton on "Audition and Colour Vision"; two by Prof. F. Keeble on "Plant Sensitiveness." On Wednesday, April 26, Prof. D. H. MacGregor gives the first of two lectures on "Industrial Relationship," and on Wednesday, May 24, Dean Inge begins a course of three lectures on "Theocracy." On Saturday afternoons there will be two lectures by Prof. O. W. Richardson on "The Disappearing Gap between the X-ray and Ultra-violet Spectra"; and three by Sir Hugh Allen on "Early Keyboard Music," with musical illustrations by Mr. Harold Samuel. The Friday evening discourses will be resumed on April 28, when Dr. Arthur Harden will deliver a discourse on "Vitamin Problems." Succeeding discourses will probably be given by Dr. M. Grabham, Dr. H. H. Dale, Sir William Bragg, Prof. W. E. Dalby, the Hon. Maurice Baring, Mr. J. Barcroft, and other gentlemen.

At the anniversary meeting of the Royal Irish Academy held last month Prof. T. H. Morgan (New York) and Prof. Jules Bordet (Brussels) were elected honorary members in the section of science.

It is stated in the *Chemiker Zeitung* of March 23 that Prof. W. Nernst will take over on April 1 the duties of Director of the Physikalisch-Technische Reichsanstalt, but will continue to act as Rector of the University of Berlin until October 15.

According to a brief despatch from Valdivia published in the *Times* of April 6, great volcanic eruptions occurred in southern Chile, to the south-east of Puerto Montt, and close to the Argentine border. They were accompanied by violent earthquakes. Much damage was caused to grazing lands on the Argentine side of the frontier, which for thirty leagues was covered with volcanic ashes.

We learn from *Science* that a meeting to initiate the Gorgas Foundation Memorial, founded in memory of the late Maj.-Gen. W. C. Gorgas, who accomplished noteworthy work in connection with tropical diseases in Panama, was held at Birmingham, Alabama, on March 4 last. Among the speakers was the British ambassador, Sir Auckland Geddes, who said: "The name Gorgas will live long after the peoples of earth have forgotten the heroes of the world's greatest war."

At the annual general meeting of the Chemical Society held at Burlington House on March 30, the following new members of council were declared elected: Vice-Presidents, who have filled the office of President: Prof. H. B. Dixon and Prof. P. F. Frankland; Vice-Presidents, who have not filled the office of President: Prof. E. C. C. Baly and Prof. T. M. Lowry; Ordinary Members of Council: Dr. C. Dorée, Dr. J. J. Fox, Prof. I. M. Heilbron Prof. J. W. McBain, Dr. W. H. Mills and Prof. J R. Partington.

Under its new constitution the Association of Assistants in Pathological and Bacteriological Laboratories is now admitting, as associate members, laboratory assistants from laboratories other than those of pathology and bacteriology. The organisation was founded in 1912, its chief object being to improve the status of the laboratory assistant by endeavouring to raise the standard of technical knowledge through the medium of an educational programme, culminating in an examination and the granting of a certificate of proficiency in laboratory technique. An official organ, *The Laboratory Journal*, is issued to members quarterly, and, in addition to Association news, the journal contains original articles and abstracts of technical interest to laboratory workers; there is also an employment bureau. From the first the founders had in mind the inclusion ultimately of all laboratory assistants in one federation, and it is hoped that the present movement will lead to the formation of sections embracing other branches of science. The Honorary Associate Secretary is Mr. F. C. Padley, 2 Eldon Place, Reading, from whom further information may be obtained.

Our Astronomical Column.

Evening Stars.—After sunset the sky now presents some interesting planets for observation. At the middle of April Venus will be brilliantly displayed in the western sky, and sets about an hour and a half after the sun has gone down. Jupiter will be visible in the south-east sky and will pass the meridian at an altitude of about 35° soon after 11 p.m. Saturn crosses the meridian 35 minutes before Jupiter, as it is situated 9° westwards.

Mars will not be visible in the early hours, but rises at midnight at the middle of the month, and will remain visible throughout the morning hours. Jupiter and Saturn may now be very successfully observed in telescopes, as they reach a fairly good altitude, but Mars is very low in Scorpio and only 15° above the horizon when due south. The latter planet will continue so far south during the ensuing summer that its markings will scarcely admit of satisfactory investigation by European observers. When the planet is nearest to the earth on June 18 next, it will be only 42 millions of miles distant from us, but its greatest altitude will not exceed 12°. In such circumstances good definition of delicate features is almost impossible when high magnifying powers are employed on telescopes.

The Distances of the Short-Period Cepheid Variables.—Bull. No. 8 of the Astr. Inst. of the Netherlands contains an important research on this subject by J. C. Kapteyn and P. J. van Rhijn. They note that the Cepheids may be divided into two classes with periods greater and less than 16 hours. Excluding those in clusters, there are 39 and 94 stars belonging to these classes respectively; the first class shows no galactic concentration, while the second shows it strongly, an argument for the relative proximity of the former. Provisional proper motions are deduced for 14 of these stars, chiefly from astrographic plates with a time-interval of some 25 years. The mean parallax deduced is 0·0065″, while the mean magnitude is 10·3; the parallax is 7·6 times as great as that given by Shapley's formula. It is pointed out that Schouten reached in 1918 the same factor 7·6 for Shapley's parallaxes of the clusters; he based this on the assumption that the luminosity curve for the stars in the clusters is identical with that found for the stars as a whole. It should be observed that neither method affects the relative distances of the clusters investigated by Shapley; it simply divides all of them by a factor. Further, the Cepheid method was only one of several used by Shapley in deducing his distances; hence it appears somewhat unlikely that they need division by so large a factor as 7·6.

Kapteyn and van Rhijn also reinvestigate the mean parallax of the long-period Cepheids, obtaining 0·0029″ from 17 stars, of mean magnitude 5·32, which is in good agreement with Shapley's 0·0034″ from 11 stars. They express the hope that trustworthy proper motions for all the 39 short-period Cepheids will be available in a few years, and ask for a suspension of final judgment on the distances of the clusters till that time.

Dr. Shapley gives some evidence on the other side in Harvard Coll. Observ. Bull. No. 765. He states that the light curves of several short-period Cepheids in the Small Magellanic cloud (mean period 0·64 days) give a mean median magnitude 16·1, closely agreeing with the value 16·2 predicted by his curve. He claims that this supports his previous estimate of the absolute magnitude of these stars.

Research Items.

An Artifice of Nectar-Sipping Birds.—In a communication sent to us by Mr. P. M. Debbarman of the Royal Botanic Gardens, Sibpur, Calcutta, he records that the flowers of *Castanospermum australe* are visited by the nectar-sipping bird *Mirafra assamica* in India. The beak of this bird is not sufficiently long to reach the nectar in the calyx cups, so the bird appears to have adopted the practice of biting off the fleshy petals which obstruct it. The tree is not a native of India but is of Australian origin, and it would be interesting to know whether any nectar-sipping birds attack the blossoms of this tree in Queensland, where it is native.

Ice in the Arctic Seas in 1921.—The annual publication of the Danish Meteorological Institute (*Isforholdene i de Arktishe Have*) shows that ice conditions last year in the Barents and White Seas were somewhat unusual. The eastern part of the Barents Sea was free from ice early in May, while in the north the edge of the pack was more northerly than usual throughout the summer. The White Sea was easily accessible and almost free of ice as early as April. On the west coast of Spitsbergen, there was considerably less ice than usual during the winter 1920–21. The fjords were frozen only for short periods and pack-ice did not appear off the coast in any quantity before May, but throughout the summer months there was a belt of loose pack off the south-west coast, which in October increased in width to some 70 miles. This occurrence was associated with the prevalence of easterly winds in the Barents Sea in summer. The same winds caused the ice to be packed against the east coast of Greenland in July and August. The distribution of ice in the Greenland Sea was normal except in this respect, which made the east coast of Greenland singularly unapproachable. On the Newfoundland banks ice-bergs were very numerous in May and again in July, when they drifted rather far south. In the Bering Sea, the edge of the pack seems to have been more northerly than usual in spring. In the Beaufort Sea a whaler reached Banks Land in August.

Seismological Stations of the World.—A valuable catalogue, and the most complete so far issued, of the seismological stations of the world has been compiled by Mr. H. O. Wood under the auspices of the Section of Seismology of the American Geophysical Union (published by the National Research Council of the National Academy of Sciences, Washington, 1921). The total number of stations is about 315, and for each is given, when known, the position and the nature of the foundation, the names of the director and of the supporting institution, the types of seismographs used and the constants of each, and the method of obtaining correct time. With regard to more than 90 of them (including all the Russian stations), however, no recent details have been communicated. Arranging the stations according to countries, we find that Japan heads the list with 55, followed by the British Empire and Italy with 42 each, the United States with 32, and Germany with 21. The instruments used are almost as diverse as the countries. The most popular is the Wiechert inverted pendulum, of which there are 72 in use with masses varying from 80 kg. to 17,000 kg. at Göttingen and Tacubaya (Mexico) respectively. Then come the Omori horizontal pendulum, extensively used in Japan, the Milne seismograph, chiefly at British stations, and the Vicentini seismographs, employed as a rule in Italy. The costly, but effective, Galitzin seismographs are in working order at not less than eight stations. Two points of some interest are the large number of stations founded during and since the war and not in neutral countries only, and the gradual replacement of the older instruments by others of more recent and accurate types.

The Cement Oilfield, Oklahoma.—A recent addition to our knowledge of the Mid-Continental Oilfield region of North America has been made by Mr. F. Reeves in Bulletin 726-B of the United States Geological Survey, wherein he deals with the geology of the Cement Oilfield, Caddo County, South-west Oklahoma. The area described occurs to the north of one of the main uplift masses (Wichita Mountains) which form such a conspicuous feature of the country bordering northern Texas, and the local tectonics of the field have intimate connection with this larger element of structure. The surface geology is mainly Permian (Red Beds), forming a vast plain surrounding the Wichita Mountains. This formation consists of shales, sandstone, gypsum and limestone, and, according to the author, has a total thickness of 1500 feet. Beneath it lies the Pennsylvanian Series, and it is presumed that the oil is obtained from the upper beds in this series, though some difference of opinion is manifest as to where the line of junction should be drawn, the transition from the older to the newer rocks being very gradual. The principal structural feature of the Cement area is the Cement anticline with its complementary synclines, the Cobb on the north and the Cyril on the south. The trend of these folds is approximately N. 70° W., a strike direction characteristic of the Wichita Mountains. The wells are located practically on the crest on the Cement fold, and have an average daily production of about 100 barrels; twenty-six wells have at present been drilled. The oil is of uniform quality with specific gravity ranging from 0·84 to 0·85. The prospects of the field are good, though it is unlikely that any startling developments will take place in the future, as the productive area is not great and the tendency seems to be for the wells to give low production with slow decline, the rate of decrease averaging 2 per cent. per month. Four gas wells have been drilled and the initial production was good, but the rate of decline of these wells was very rapid. The Bulletin itself is quite up to the usual standard of Survey publications in the matter of descriptive text and particularly in the maps and plans accompanying it.

Land and Sea Breezes in the Gulf of Lions.—An article by Prof. M. Moye is given in the *Meteorological Magazine* for March on land breezes and sea breezes on the French and Catalonian coasts of the Mediterranean Sea. They are stated to be a distinctive feature of the summer climate in these parts, and are said to be much more marked than on the Channel and Atlantic shores. From a discussion by Prof. E. Fontséré, it is shown that at Barcelona sea breezes begin in March, when they blow on about four days out of ten. In April and May they blow on more than six days out of ten, and from July 15 to August 15, sea breezes are recorded on nine days out of ten. In September they are less frequent, and by the end of October they practically disappear. At Montpellier sea breezes are said to be rare before mid-May and after September. The sea breezes generally begin after a short period of calm. During the night and in the early morning land breezes blow gently. The sea breeze begins from the south and south-

west, and the direction is from south-west or west-south-west in the afternoon. The land breezes at night blow from north-west or north. Sea breezes generally blow more strongly than land breezes. A normal sea breeze at Barcelona corresponds with 4 or 5 on the Beaufort wind-scale, whilst at Montpellier the breeze is rather lighter, not exceeding force 3 or 4. Land and sea breezes are said to be essentially surface currents and they are supplemented by a return circulation in high atmosphere. These points have been tested by pilot balloons and the results given are decidedly instructive.

United States Temperatures. — The U.S. *Monthly Weather Review* for November 1921 has an article on "Some Characteristics of United States Temperatures" by Prof. Robert De C. Ward, of Harvard University. The author has had access to maps prepared by the U.S. Weather Bureau for the new Atlas of American Agriculture. The temperatures are not reduced to sea level. In the opinion of the author the isothermal maps of the United States will supersede all previous maps and will for years to come remain the "standard set." Isothermal lines are given for each 5° F., and those for midwinter and midsummer run fairly smoothly and symmetrically to the east of the Rocky Mountains, but the effects of the Appalachian topography warp the local irregularities of the lines. Over the western plateau and mountain area, the isotherms are most irregular, and it is there that the new charts, which show actual temperatures, are so great an advance on those previously drawn. The greatest differences in temperature in different parts occur in the winter. In January, going southwards the temperatures increase about 2°·5 for each degree of latitude. Very different conditions exist in midsummer, when the distribution of temperature is far more uniform and the difference of temperature for each degree of latitude amounts only to about 1° F. Highest and lowest "record" temperatures are given on separate maps produced from the results at about 600 stations. These extreme temperatures are of considerable interest, and if they do not show the world's highest and lowest readings, they give very valuable results. In the United States, especially in the eastern parts, very low temperatures commonly penetrate far to the south into latitudes where the winters are distinctly mild.

Submarine Periscopes.—The current number of the Transactions of the Optical Society contains a paper by Dr. Alexander Gleichen on the path of rays in periscopes having an inverting system comprising two separated lenses, in which results are given of a theoretical investigation carried out by the author for Messrs. C. P. Goerz of Berlin-Friedenau. The paper is devoted generally to the design of periscopes as regards the best arrangement and sizes of the various optical parts involved, with the object of making the best possible use of the available space, which in the case of submarine periscopes particularly is very limited. The characteristics of these instruments are their comparatively great length and small diameter. In particular it is shown how the magnification, the field of view, and the illumination in the centre and at the edge of the field of view, depend on the length and diameter of the instrument, in order to derive therefrom the most advantageous optical arrangement. A feature of submarine periscopes which limits the design to an important extent is the reduction of the diameter of the upper portion which may be extended above the surface. Formulæ for the determination of the path of the rays in periscopes of this type are given and also a brief statement regarding the external form of the submarine periscope.

Crystal Structure of Common Elements.—In a paper published in the Journal of the Franklin Institute for February under this title, A. W. Hull gives a very useful summary of the results of X-ray crystal analysis. The methods of analysis which were first developed (analysis by means of a Laue photograph, or with the X-ray spectrometer) can be used only if a single homogeneous crystal of appreciable dimensions is available. It was impossible to examine the structure of a large number of the elements and simple compounds, which could be obtained only in a finely divided crystalline form, until the "powder method" of analysis was developed by Debye and Scherrer, and by Hull. A mass of powdered crystalline material is placed in the path of a narrow beam of monochromatic X-rays and the crystal structure is deduced from the manner in which the rays are diffracted. The technique of the powder method of analysis has been brought to a very high degree of perfection by Hull, who has examined a large number of elements and compounds. We now know the crystalline structure of thirty-five of the elements, twenty-nine having been determined by Hull himself. A number of binary compounds have recently been analysed by Davey, using the Debye-Hull method. A list of all crystals whose structures have been completely determined is given by Hull. The powder method of analysis will certainly become a most powerful means of studying the structure of solid bodies. It can be applied to any crystalline substance, and in addition, it can be used to analyse constituents of a mixture of crystalline bodies, so that to the metallurgist it will be of the highest importance. The paper concludes with an interesting discussion of "atomic diameters."

The Lighting of Public Buildings.—An interesting paper on this subject was read by Messrs. E. H. Rayner, J. W. T. Walsh, and H. Buckley of the National Physical Laboratory, at the meeting of the Illuminating Engineering Society on March 28. The paper was devoted mainly to experiments undertaken in co-operation with H.M. Office of Works, one noteworthy installation being the semi-indirect lighting in the new Pensions Offices at Acton. The tabulated data show that the level of illumination provided in public buildings has arisen considerably during recent years, values from 3 to 4·5 foot-candles now being general. Another section of the paper was devoted to some experiments on the lighting of picture galleries, where the avoidance of reflected images in the glass on pictures is a difficult problem. Diagrams were presented showing a new arrangement of the skylights which, while occasioning some loss in light, seems to give a much more satisfactory distribution of illumination. The authors also described a special building erected at the National Physical Laboratory for the purpose of experiments on illumination, which has some interesting features. Following the presentation of the paper Capt. J. W. Liberty, Public Lighting Inspector to the City of London, showed a number of photographs of recent lighting installations in certain public buildings, where architectural and decorative considerations play an important part. Amongst such interiors may be mentioned the Guildhall, the Marylebone Town Hall, and the new Port of London building. Some of these interiors, notably those panelled in very dark walnut, present interesting lighting problems. The arrangement adopted in the main office at the Port of London building, where gas-filled lamps giving 20,000 c.p. are assembled in a vast white dome, is particularly striking, and it is hoped to present fuller details of this installation when completed.

Auxiliary International Languages.[1]

By Prof. F. G. Donnan, F.R.S.

At the present day the rights of all nations to unity, to the preservation and independent development of national life and customs, are fully recognised and admitted. Partly as a result of the war, long dormant hopes and moribund languages have awakened to a new period of life and activity. We live amidst a remarkable efflorescence of national diversity and national pride.

At the same time, the material means of intercommunication by land, sea, and air are rapidly increasing in speed, efficiency, and cheapness. You can lunch quietly and leisurely in Amsterdam and the same afternoon have tea with a friend in London. Science and industry are advancing with giant strides, and in rapidly increasing measure all nations are taking part in this work. The modern world is thus a vast arena of conflict between separating and intermixing forces. In the loom of life a myriad coloured threads are intertwined in the strange fabric of modern civilisation. But where are the integrating influences that will give us that *unity in diversity* which all wise men seek?

It is not a monotonous unison of thought that I mean, but a harmony of independent notes—an integration, and not a unification, of separate ideas. What is it that, while conserving the independent life of nations, will produce a common liberality of thought and action? There is only one answer—the intercommunication, the internationalisation of thought. Men have dreamed of a common political organisation of the world, of a human family one in government, speech, and religion. Such things may perhaps come to be, but they lie in the shadowy realm of a very distant future. The practical problem of to-day is the problem of mutual intercomprehension, of unity of understanding, amidst variety of thought, speech, and action. The solution of this problem lies in the existence of an auxiliary language common to all the nations of the world; what we may therefore call an auxiliary international language.

As late as the eighteenth century, Latin served the purpose of an auxiliary international language for the learned world, whilst French has long held sway as the common language of diplomacy (though recent events have tended to give English an equal rank). It may come to pass in the distant future that one of the great modern languages will be gradually accepted by all nations as a common auxiliary tongue known to and used by all. Many Englishmen fondly believe that this high destiny is reserved for their mother language. The very unphonetic character of English spelling presents a great difficulty in this connection.

Those who have given the greatest amount of study to this subject have come to the conclusion that the world will not accept any living national language as a common medium of intercommunication. Feelings of national jealousy, prestige, and advantage are too strong. The international auxiliary language must be *neutral*. It must also be simple and regular, and simplicity and regularity are not qualities possessed by any living national language. From various points of view Latin would satisfy the condition of neutrality, and there are some who urge the claims of this language. But apart from other obstacles, the intrinsic difficulty of Latin is too great.

The object of an auxiliary international language is not to displace or replace existing languages, but to protect and supplement them. These qualities of neutrality, simplicity, regularity, and compatibility can be obtained only by means of an *artificial auxiliary language*. Now this word *artificial* shocks and frightens people. We are so accustomed to the historical and analytical treatment of languages that we have never dreamt of the possibilities of synthesis. The chemists and physicists have analysed nearly all the things they have found in this world. But if they had rested content only with analysis, the practical world would have much less to thank them for. We may not like synthetic butter and synthetic milk, but we have no objection to synthetic soap or synthetic glass. Why not then a synthetic language? So far as the languages of North and South America and of Western Europe are concerned, the problem is mainly one of the synthesis of existing elements, since amongst these languages there exists already a very large international vocabulary. As Dr. Cottrell has aptly expressed it, our problem is nothing less and nothing more than the science of synthetic linguistics. Looking at the matter from this point of view, we see that the word "artificial" is a misnomer. It is true that the first attempts to solve the problem of an auxiliary international language might be fitly termed artificial. They take us back to the seventeenth century. Impressed by the logical manner in which mathematical symbolism represents complex trains of thought in a form at once intelligible to mathematicians of all countries, some of the greatest philosophers and mathematicians of that century conceived the idea of an international language which would be a logical algebra of general thought. Descartes in 1629 discussed this idea in a letter to his friend Mersenne. Leibniz devoted many years to the problem, though he considered that for immediate practical purposes a simplified and regularised grammar applied to the word elements of Latin would provide the best solution.

Language systems of this sort are called "philosophical" or *à priori*. In their construction we might endeavour to make a list of all the primary ideas, and assign arbitrary written symbols, which may be also pronounceable sounds, to these. With the various permutations and combinations of these symbols we might then form all derived ideas. It is clear that from a very few symbols we can easily, by means of their permutations and combinations, form thousands of derivatives. When the number of primary ideas or elements is relatively small, such systems are of great use and are largely used. The various special codes used in international commerce are examples of this method. Another example of such an international code language may be seen in the nomenclature and symbolism of chemistry.

Thus "H_2SO_4" and "para-nitro-anilin" are intelligible to chemists of every nationality. But for general purposes such systems would become exceedingly complex. Moreover it would be very difficult to draw up a simple and fixed table of primary and fundamental ideas, for although the fundamental data of sense may remain invariable, the intellectual activity of the human mind is constantly penetrating the screen of sense-perception. Thus new concepts and ideas in accord with our progressive discovery of the real structure and activity of the world are constantly being formed.

The inventors of *à priori* philosophical languages have, however, usually proceeded in a somewhat different fashion, their object being to construct a vocabulary that would be based on a rational system of classification corresponding to our knowledge of things. Thus in the seventeenth century a

[1] From a discourse delivered at the Royal Institution on Friday, March 24.

Scotchman, George Dalgarno, and also the celebrated Bishop Wilkins—one of the founders of the Royal Society—produced two such philosophical systems. That of Bishop Wilkins was entitled "The Essay towards a Real Character and a Philosophical Language" (London, 1668). In the eighteenth century the disciples of Condillac, the Ideologists, took up the problem of an artificial language considered as a classification and notation of ideas; whilst in the middle of the nineteenth century the learned Spanish professor, Bonifacio Sotos Ochando, published a very perfect system of this type, in which both the grammar and the vocabulary were very fully worked out.

In his "Lectures on the Science of Language" delivered before the Royal Institution fifty-nine years ago, Max Müller discussed the possibility of an artificial language, and gave an account of the system of Bishop Wilkins. Speaking in this connection he said: "It is the fashion to laugh at the idea of an artificial, still more of a universal language. But if this problem were really so absurd, a man like Leibniz would hardly have taken so deep an interest in its solution. That such a language should ever come into practical use, or that the whole earth should in that manner ever be of one language and one speech again, is hard to conceive. But that the problem itself admits of a solution, and of a very perfect solution, cannot be doubted."

In order to understand the method employed by Bishop Wilkins, I give here the basis of his system of classification:—

System of Bishop Wilkins.

	A. Transcendental Notions	Divided into 6 Genera.
Five Categories of Logic	*B.* Substances *C.* Quantities *D.* Qualities. *E.* Actions *F.* Relations	Divided into 34 Genera.

These 40 fundamental genera were subdivided into numerous species, and to all these genera and species letters of the alphabet were assigned in a regular ordinal manner. Thus the genus "element," one of the types of "substance," was denoted by De. Now Bishop Wilkins followed the peripatetic philosophy and divided the genus element into the species earth, air, fire, and water.

Substance

Element = De

Fire = Deb

Flame = Deba

De = Element; Due = elementary.
Do = Stone; Duo = stony.

Fire thus became Deb, and flame, a variety of fire, became Deba. Grammatical function was indicated by appropriate letters, *e.g.* De = element, Due = elementary. Do = stone, Duo = stony.

We can perceive here two of the fundamental objections to all such philosophical systems. In the first place all such classifications are fleeting and transient. At best they can but reflect the knowledge and science of their day. But as this is constantly changing there is no finality. We no longer accept the earth, air, fire, and water of the Aristotelian-scholastic philosophy as a satisfying classification of elementary substances. Even the chemical elements of twenty-five years ago are dissolving before our eyes into the electrons, protons, and neutrons of a newer philosophy. But even were there a finality of knowledge, such classificatory symbolisms would be very difficult to memorise. We should have to remember not only the symbols and their meanings, but also the whole ordinal system of assignment. In practice we should have to learn the system empirically as we do natural living languages. Thus all the hoped-for advantages would disappear. To a child *Deba* might soon come to mean flame, but if we came across this mysterious word in later life we should have painfully to de-code it.

The modern era, the era of synthetic or *à posteriori*, as contrasted with purely *à priori* languages, began with Volapük. This was the discovery of Monsignor Johann Martin Schleyer, a Roman Catholic priest of Baden in Germany, and was given to the world towards the end of the year 1880. His vocabulary consisted of root-words, derived words, and compounds. Schleyer endeavoured to borrow his root-words from the international stock, so that the greatest number of persons might have the fewest unfamiliar words to memorise. He stated himself that the Volapük Lexicon was based mainly upon the English language, because it was spoken by 100 million people. Unfortunately for the 100 million, these roots were so changed by Schleyer that a very large number of them became unrecognisable in the written language. There were several reasons for this. His system was a phonetic one, but the sounds corresponding to several of his letters were so chosen as to destroy the international appearance of the roots. No stem or root which was declinable could end in the sibilant consonants *c, j, s, x*, and *z*, since the plural was formed by the letter *s*. Monsignor Schleyer held that the letter *r* offered such difficulty of pronunciation to children, Englishmen and Chinese—a majority of mankind—that it had to be very largely eliminated. For *r* he substituted very often the letter *l*. Finally he made his roots as monosyllabic as possible.

The net result of these transformations was that many roots chosen from English, or other languages, on account of their internationality, became unrecognisable.

Volapük belongs to the class of "mixed" languages in which borrowed and arbitrary elements are more or less logically combined. Nevertheless, in spite of its many difficulties and its *à priori* elements, it represented an enormous advance on the purely artificial or *à priori* systems of Wilkins, Sotos Ochando, and many others. It presents us with the first great attempt to build up from a small stock of existing root-words a synthetic auxiliary international language based on an autonomous system of word-formation and on a perfectly regular inflexional grammar. In its day, it had a great success. At first it spread slowly, but about 1885 it was actively taken up in France, its chief partisan and exponent being Dr. Auguste Kerckhoffs, professor of modern languages at the School of Higher Commercial Studies in Paris. From France it spread to all parts of the world. Three international Congresses were held, the third taking place at Paris in 1889. At that time there were 283 Volapük Clubs spread all over the world, 316 text-books had appeared, and there were some 30 periodicals appearing in Volapük or dealing with it.

The disappearance of Volapük was due largely to the internal dissensions of its partisans, some of whom, led by Dr. Kerckhoffs, wished to make it simpler and more adapted to the needs of commercial life.

These attempts at reform were, however, resisted by the learned originator. No doubt his system

was too complicated and intricate for the majority of people. Moreover, those who took an interest in the problem of an auxiliary international language were soon provided with the much simpler and more practical Esperanto.

The author of this language, Louis Lazarus Zamenhof, was born in 1859 at Bielostok, in what was then Russian Poland. Perceiving the racial and linguistic hostilities of his native country, as a young school student in Warsaw he already dreamed of a universal neutral language and of a universal brotherhood founded thereon. He graduated as a physician at Warsaw, but during the six years of his university course he worked constantly at his secret project. At first he thought of reviving Latin, or of constructing an *à priori* or philosophical language. It was the study of English, however, that first showed him what could be done by means of a simple grammar, and how stems of different origins could be utilised in the construction of a harmonious and self-contained language. In 1885 his work was complete, but it was only in 1887 that he found a publisher. In that year there appeared in Warsaw a Russian pamphlet describing "La Lingvo Internacia de la Doktoro Esperanto," The international language of Dr. "Hopeful." In 1900 there appeared the "Universala Vortaro de la Lingvo Internacia Esperanto," by L. Zamenhof. In this dictionary the equivalents were given in five languages. The pseudonym "Esperanto," adopted originally by Dr. Zamenhof, has been transferred to the name of the language. The progress of Esperanto was at first slow. But in 1898, when the French took the lead, expansion became rapid. The Marquis Louis de Beaufront became the leader of this movement. In 1914, when the war broke out, there were over a hundred Esperanto periodicals, some appearing in Esperanto only, others in Esperanto and a national tongue. In 1905 an international Convention or Congress was held at Boulogne. Since then twelve other international Congresses have been held, the thirteenth at Prague in 1921. As an international auxiliary language, Esperanto has had an unparalleled success. It has done more to spread the idea of the need for and the possibility of an auxiliary international language than any other project.

The fundamental ideas of Zamenhof were very largely those of Schleyer: a phonetic system, a regular method of pronunciation, a vocabulary of root-words drawn from the international treasury, an autonomous system of word-formation, and a perfectly regular grammar. In other words, an *à posteriori* synthetic language. But in practice the contrast was enormous. Zamenhof did not transform and distort his international roots as Schleyer did. He carried out the choice of international stems on a much broader basis. His grammar was enormously more simple and practical. The inflexional richness of the work of the learned and scholarly Schleyer disappeared, and together with it most of his *à priori* and arbitrary elements. Zamenhof's autonomous system of word-derivation by means of affixes of fixed and definite meanings, and by means of root-combinations, was immensely superior. The arbitrary characteristic endings corresponding to a classification of ideas, a relic in Volapük of the earlier *à priori* philosophical systems, disappeared in Zamenhof's language. The idea of using only monosyllabic roots was given up, and so the international appearance of these could be much better preserved.

In spite of many obvious and indeed glaring defects, Esperanto is undoubtedly, so far as numbers are concerned, the greatest and most successful linguistic experiment that the world has yet seen. Let us not criticise too severely the work of a man who was neither a great scholar nor a great professional philologist, but let us rather admire the splendid effort which he made. His work has been of the greatest service in demonstrating to an indifferent world the practical possibility of an auxiliary international language.

So great was the interest taken in this branch of science at the Paris Exhibition of 1900, that under the leadership of M. Leau, a French professor of mathematics, a number of men of science and delegates from learned societies were gathered together, and on January 17, 1901, the "*Delegation for the Adoption of an Auxiliary Language*" was founded. After a great deal of preliminary work on the subject, the matter was submitted, through the kind offices of the Imperial Academy of Sciences of Vienna, to the International Association of Academies, which on May 29, 1907, declared itself incompetent to deal with the question. The Delegation then proceeded itself to elect a special Committee to study the problem. This Committee embraced a number of distinguished authorities on science and linguistics, and included the two secretaries, Profs. Couturat and Leau. After eighteen sittings held at the Collège de France, the following decision was arrived at:

"None of the proposed languages can be adopted *in toto* and without modification. The Committee have decided to adopt in principle Esperanto, on account of its relative perfection and of the many and varied applications which have been made of it; *provided* that certain modifications be executed by the Permanent Commission, on the lines indicated by the conclusion of the Report of the Secretaries and by the project of Ido, if possible in agreement with the Esperantist Linguistic Committee."

It appeared later that the "project of Ido" was an anonymous pamphlet proposing a number of reforms in Esperanto, the real author of which was the Marquis de Beaufront, until that time the most eminent supporter of Esperanto in the world. Messrs. Couturat and Leau had made a most exhaustive and scholarly study of all known auxiliary languages, their labours being embodied in a very masterly book entitled "Histoire de la Langue Universelle," and also in another one entitled "Les Nouvelles Langues Internationales." Their Report to the Committee indicated very clearly the lines along which Esperanto could be improved.

As the Esperanto Linguistic Committee declined to collaborate, the Committee of the Delegation appointed a Permanent Commission to carry out the reforms which they had in view, and as they were unable to use the name Esperanto, the reformed Esperanto was called "Ido."

In its basic ideas Ido is a language of the same type as Esperanto. It is a great pity that all parties could not have combined at an early stage in the development of Ido. If I may be allowed a personal opinion, I will say that most, if not all of the Ido improvements appeal to me very strongly. If we are to choose a language of the Esperanto type, and if the choice lies only between Esperanto and Ido, I would choose Ido. I do not say this for any propagandist purposes, and I say it with a full appreciation of the splendid early work of Dr. Zamenhof. But at the same time I have an equally great admiration for the splendid later work of Prof. Couturat and his collaborators.

Ido, like Esperanto, has had a very great success, and has been very thoroughly developed. Many general and technical dictionaries have been worked out. Before the war there appeared ten or twelve periodicals dealing with, or written in, this language. The International Ido Academy has done very fine

work in bringing it to as high a state of perfection as possible. Very many Ido clubs and societies have been formed in all parts of the world, and already a very considerable literature exists. We may say that the Ido, like the Esperanto, movement, has done immense service in familiarising the world with the practicability of an international auxiliary language. Both these great linguistic experiments are of profound interest and importance.

I must now lead your thoughts away from Esperanto and Ido and back to the International Academy for a Universal Language, which was founded by the two international Volapük Congresses of 1887 and 1889. This Academy continued to exist, and set itself to the task of reforming Volapük. Very important and scholarly work was done by Mr. Rosenberger, a Russian engineer, and his collaborators (Rosenberger was Director of the Academy from 1893 to 1898). They produced a vocabulary of root-words based on the principle of maximum internationality. The greater part of these roots are common to at least four of the seven chief languages — German, English, French, Italian, Russian, Spanish, and Latin. Largely as a consequence of the inclusion of Latin, the result was an almost exclusively Neo-Latin vocabulary—one much more Romanic than that of Esperanto. A very simple grammar and a regular system of word-derivation by means of derivative affixes were introduced. But autonomous word formation was not allowed to exclude international derivatives.

Thus was produced about 1903 the Language "Idiom Neutral," the descendant of Volapük, though scarcely any trace of the parental features remained.

Idiom Neutral has not achieved the practical success of Esperanto and Ido. This may be because it came too late. It appeals to educated people more than Esperanto and Ido on account of its more homogeneous vocabulary, which is practically exclusively Romanic. But it has not been so fully developed as Esperanto and Ido. As a separate and independent project, it may be said to have disappeared with the death of Mr. Rosenberger in 1918.

A language of the Neo-Latin type, somewhat similar to Neutral Idiom, is the "Panroman" (or "Universal") of the German positivist and pacifist, Dr. H. Molenaar. Various attempts, such as those of Mr. Henderson and of Dr. Rosa, have been made to introduce a sort of simplified Latin. But the man who has defined most clearly the Neo-Latin principle, and who has worked not only the hardest in this field but has also grouped and organised many isolated workers of kindred views and affinities, is Dr. Giuseppe Peano, professor of mathematics in the university of Turin. In 1908 he became Director of the International Language Academy. In the "Discussiones" of that body he has published from year to year the work of himself and many collaborators. A very large amount of scholarly work has been done in the discovery of the international vocabulary common to Latin, Italian, French, English, and German. The result of this etymological study may be seen in Professor Peano's important "Vocabulario Commune," the second edition of which appeared in 1915. Following the indication given by Leibniz, Peano has built on an exclusively Neo-Latin basis so far as the main vocabulary is concerned, though modern words acquiring international usage may be accepted.

For many scientific purposes Peano's flexionless Latin is ready for use. He has himself employed it for many years in his own journal, *The Mathematical Review.*

The true solution of the problem may consist in selecting the most international roots according to the fashion of Peano, but also the most international affixes of derivation. With these natural elements, derivatives and compounds will then be formed according to simple and invariable rules. Thus the advantages of the Neo-Latin or Anglo-Latin vocabulary of stems will be combined with the regular and autonomous word-derivation of Ido. This is the view held by Prof. Guérard, who has just published a most valuable book entitled "A Short History of the International Language Movement" (Fisher Unwin, 1922). As Prof. Guérard points out, these two sets of fundamental ideas are embodied in the language project of M. Albert Michaux, entitled "Romanal."

Needless to say, Romanal is not the last word on the subject, nor is it free from debateable points. But it represents the combination of an "etymological Anglo-Latin" root vocabulary with regularity of word-derivation and simplicity of grammar.

In the preceding discussion I have endeavoured to give a very brief account of some of the principal efforts to solve the problem. The large amount of research work already done and the practical success of Esperanto and Ido prove that the problem is not an insoluble one. At first one might be inclined to think that the production of an international auxiliary language is a sort of parlour game, or at best a pure matter of caprice. Attentive study of the problem shows that this is quite a false view. Whatever may be the final solution, it is already clear that some of the fundamental principles have been elucidated. There *does* exist a science of synthetic linguistics, compounded of logic, psychology, and philology. It has been argued that the field hitherto traversed, at all events in the later systems, is too narrow; that the so-called international vocabularies are not really international and apply at best only to two groups of existing languages. What comfort, it is argued, can a word such as "amico" bring to the Basques, Finns, Hungarians, Turks, Japanese, Chinese, etc.? What special comfort, I would then ask, does the learning of English, French, German, Italian, Spanish, Dutch, Swedish, and Russian bring to a young Japanese gentleman? Are we then to go back to Sotos Ochando and bring comfort to nobody? I think not. But the objection is not one to be passed over lightly. It may be that the world will require more than one auxiliary language. Two, or even three, would be better than the necessity of having to learn a hundred living languages. Only time and prolonged study and investigation can settle questions of this order. The whole civilised world must collaborate in this investigation. There is plenty of time. We have been using an alphabet for, say, eight or ten thousand years at most, and as this planet is reckoned to be over a thousand million years old, it will probably continue to be habitable for some considerable time.

Meanwhile the problem is a very pressing one. Those who have to do with science, industry, and commerce feel this very acutely. Before the war I attended several international scientific congresses. On these occasions it was open to any one to speak in English, French, German, or Italian. When the language of the speaker or lecturer changed, one half of the audience usually adjourned to the refreshment bar. I could follow German, but when it was a case of Italian or Parisian French I also used to get thirsty. I am going to an international scientific congress in June of this year. The representatives of at least thirteen different nations will be present, and I expect at least four languages will be used. As the language of the country where the congress is to be held is not one of these, one ought really to know five languages. I am glad to say that the civilised world is at last beginning to take a real interest in this

problem. We may, indeed, say that, since the war, the whole question has entered on a new phase. Learned and scientific bodies of international influence and repute are beginning to study the matter seriously. The present organised movement in this direction may be considered as dating from the adoption, by the International Research Council at their meeting at Brussels in July 1919, of the following resolutions:

(*a*) That the International Research Council appoint a Committee to investigate and report to it the present status and possible outlook of the general problem of an international auxiliary language.

(*b*) That the Committee be authorised to co-operate in its studies with other organisations engaged in the same work, provided that nothing in these resolutions shall be interpreted as giving the Committee any authority to commit the Council to adhesion to or approval of any particular project.

This Committee is now at work. Its chairman is Dr. F. G. Cottrell, and its headquarters are at the offices of the National Research Council of the United States, 1701 Massachusetts Avenue, Washington, D.C. This Central Committee has already done an immense amount of work in securing the organisation of committees and working groups in the national academic organisations and educational institutions, and in co-ordinating this work and serving as a clearing-house for the exchange and distribution of information and plans. The first national response to the appointment of the International Committee was by the British Association for the Advancement of Science, which, at its Bournemouth Meeting in September 1919, appointed a Committee "to study the practicability of an International Language." This British Committee has been very active, and at the Edinburgh meeting of the British Association in September last, presented its report. Its conclusions may be summarised very briefly as follows:

(1) Latin is too difficult to serve as an international auxiliary language.

(2) The adoption of any modern national language would confer undue advantages and excite jealousy.

(3) Therefore an invented language is best. Esperanto and Ido are suitable; but the Committee is not prepared to decide between them.

The Committee is continuing to study the problem. The American Association for the Advancement of Science appointed a Committee in April 1921, and this Committee has presented a Report, which was accepted by the Council of the Association at Toronto on December 29 last. The Committee recommended that the American Association for the Advancement of Science:

(*a*) Recognises the need and timeliness of fundamental research on the scientific principles which must underlie the formation, standardisation, and introduction of an international auxiliary language, and recommends to its members and affiliated Societies that they give serious consideration to the general aspects of this problem as well as direct technical study and help in their own special fields wherever possible.

(*b*) Looks with approval upon the attempt now being made by the National Research Council and the American Council of Learned Societies to focus upon this subject the efforts of those scholars in this country best fitted for the task, and to transmit the results to the appropriate international bodies.

(*c*) Endorses the heretofore relatively neglected problem of an international auxiliary language as one deserving of support and encouragement.

(*d*) Continues its Committee on International Auxiliary Language, charging it with the furtherance of the objects above enumerated, and reporting progress made to the Association at its next meeting.

The American Council on Education, the American Classical League, the American Philological Association, and the National Research Council of America have also appointed Committees. Furthermore, the American Council of Learned Societies has authorised the appointment of delegates to confer with the Committee of the National Research Council. Thus the national American representatives of science and the humanities are uniting to study the problem.

Both the French and the Italian Associations for the Advancement of Science have also appointed Committees to examine and report on the international language question.

On September 13 last, the following resolution was presented to the Assembly of the League of Nations by delegates representing twelve States:

"The League of Nations is well aware of the Language difficulties that prevent a direct intercourse between the peoples, and of the urgent need of finding some practical means to remove this obstacle and help the good understanding of nations;

"Follows with interest the experiments of official teaching of the international language Esperanto in the public schools of some members of the League;

"Hopes to see that teaching made more general in the whole world, so that the children of all countries may know at least two languages, their mother tongue and an easy means of international communication;

"Asks the Secretary General to prepare for the next Assembly a Report on the results reached in this respect."

With regard to this motion, the special Committee dealing with the inclusion upon the Agenda of Motions submitted to the Assembly reported to that body on September 15 last, as follows:

"The above-mentioned delegates have proposed the introduction of Esperanto as an auxiliary international language into public schools, in order to facilitate direct intercourse between all nations throughout the world.

"The Committee are of opinion that this question, in which an ever-increasing number of great states are interested, should be attentively studied before it can be dealt with by the Assembly."

As a result of this, the secretariat of the League have been instructed to investigate the experiments already made and ascertain the actual results attained.

On November 20 last, some Swedish gentlemen interested in the question of an international language formed a Committee to promote this subject and to unite the various interests concerned. This Committee has brought the matter before the Swedish Parliament and has also addressed a request to the League of Nations.

From all this it will be evident that the existence of the problem, and the urgent necessity for its study and investigation, are now fully admitted and recognised by the learned, scientific, and political organisations of the highest national and international status. Before definite action can be taken by national governments, there must be, however, another period of prolonged and exhaustive linguistic research and experiment. This work must be, as we have every reason now to hope and expect, co-ordinated and supported internationally. Those who have laboured manfully in the past, and the many who have given their adherence to this or that special solution, must be prepared to co-operate without bias and without sorrow. The subordination of self and of the most dearly held, the most beloved possessions of the mind in the interest of intellectual advance and the common good of humanity is the spirit of true science.

The Properties of Powders.

CONSIDERABLE interest attaches, both on the scientific and on the technical side, to the study of powders which are sufficiently fine to differ markedly in their properties from massive crystals, while they are sufficiently coarse to differ equally widely from colloidal suspensions. One important property of powders, namely the caking of salts (a phenomenon which was responsible for the disastrous explosion at Oppau), was discussed at a joint meeting of the London Section of the Society of Chemical Industry and of the Faraday Society on March 1, 1920. This has now been followed up by a joint meeting of the Faraday Society and the Oil and Colour Chemists' Association, held at Burlington House on March 9 last, when the material presented was sufficiently abundant to call for an adjourned discussion on March 23.

The principal subject discussed was the grading of powders by elutriation, a process which has proved of great value to the geologist and to the agriculturist, as well as to the manufacturer of pigments and of food products where artificial grinding is required in order to produce minute subdivision.

(a) 4 mm. (b) 5 mm. (c) 6 mm. (d) 7 mm. (e) 8 mm. per sec.

FIG. 1.—Elutriation of Barytes. (× 50.)

The formal papers presented to the meeting were four in number. Prof. Lowry and Mr. L. P. MacHatton, in a paper on "The Grading of Powders by Elutriation," submitted a new series of experimental data as to the diameter of the particles of barytes and of quartz which are just lifted by a vertical current of water at velocities ranging from 4 to 8 mm. per second (Fig. 1). The data for barytes are more concordant than those for quartz, probably because the particles of barytes are, in the main, cleavage-fragments of fairly uniform shape, whilst in the case of quartz the natural conchoidal fracture produces much more irregular particles. In the case of barytes it was possible to show that the use of a vertical tube one inch in diameter lifts particles which are 5 per cent. smaller than when a half-inch tube is used; but the grading is also much more uniform as a result of the more uniform velocity of the water in the tube. The temperature-coefficient was also measured and shown to correspond with a decrease of 0·4 per cent. only in the diameter of the particles for each degree of rise of temperature; and an empirical relationship was deduced between the velocity of the water and the size of the grain of barytes lifted by it.

Prof. Boswell presented a paper on "The Separation of the Finer Constituents of Sedimentary Rocks," in which the geological applications of elutriation are described. One of the principal problems here is to devise a method of summarising the mechanical analysis of a sediment, containing particles of many different sizes, in such a way that the results can be expressed by means of one or two numbers. The use of a single number is impracticable, since in addition to the fineness of the material, its uniformity must be represented by a separate coefficient. A satisfactory solution appears to have been provided by Dr. H. A. Baker, who makes use of the term "equivalent grade" to express the average of the diameters of the particles, whilst a "grading factor" serves to express the deviation of the particles from the average. Prof. Boswell has had much experience in the practical application of elutriation, particularly in the mechanical analysis of the sands and rocks used in glass-making, and his notes on the difficulties and errors encountered in the process are of considerable value. Dr. J. W. French, who has made use of water-separation for the grading of emery and carborundum for use as polishing powders in grinding lenses, contributed to the same meeting a paper on "Abrasives and Polishing Powders for Glass."

Dr. R. S. Morrell, the president of the Oil and Colour Chemists' Association, opened the discussion, by emphasising the value of elutriation to colour-users, as a method of controlling the materials which they purchased from the pigment-makers and grinders.

The adjourned discussion was opened by Dr. C. A. Klein of the Brimsdown White Lead Company. While Prof. Lowry had been working with a range of sizes down to about 0·07 mm., Dr. Klein's work had dealt with grades in which this was more nearly the maximum than the minimum size of the particles; they therefore presented greater experimental difficulties, more particularly as a result of flocculation. In addition to describing a number of points in connection with the practical use of the elutriator, Dr. Klein stated that a specification had actually been put forward by a user of pigments who was calling for the supply of some hundreds of tons of a product in which the largest particles would have a diameter not exceeding 0·1 mm., whilst the average size of the particles was not to exceed 0·027 mm. This specification was being worked to and material conforming to it could be supplied.

Prof. Lowry then showed "A New Elutriator for Rapid Use," especially adapted for use in factories. The gravimetric determination of the residue of coarse particles is here replaced by a simple measurement of the height of the column of grit in a narrow tube, and tests can therefore be made even where the ordinary facilities of a chemical laboratory are not available. Lieut.-Col. J. V. Ramsden, of Shropshire Mines Ltd., stated (at the previous meeting) that with the help of this instrument he had been able, whilst using the same grinding plant, to reduce the residue in ground barytes from 6 per cent. to 0·5 per cent. Prof. Lowry added that since this instrument was introduced two years ago the relative merits of British and imported samples of ground barytes had been reversed completely, with the result that the finest products that he had tested recently were of British manufacture.

Mr. W. J. Palmer referred to the practical importance of fine grinding in the paint industry, both in the preparation of enamels and as a means of preventing the hard setting of paint in cans which were sent abroad or stored for some years before being used. Mr. Noel Heaton contradicted the general impression that the ball-mill tends to produce round particles, since when the glass was ground in this way, even to 0·003 or 0·004 mm. diameter, the particles when examined by the microscope had the normal appearance of broken glass and were not in the least degree rounded.

Dr. R. Lessing mentioned some applications of elutriation in connection with the fire-brick, coal and metallurgical industries. Its application to metallurgy was described by Mr. Holman in connection with tin slimes, where a loss of 10 to 15 per cent. was traced to the carrying away of very fine particles in a current of water.

Mr. Tate, of the Government Laboratory, referred to elutriation as a process of analysis in the separation of cocoa from husk in the ground product; a paper on this aspect of the subject was also submitted by Mr. R. Whymper of Messrs. Peek, Frean & Company.

Mr. B. A. Keen, of Rothamsted, criticised the method of elutriation as applied to the mechanical analysis of soils, largely on the ground that the shape of the particle was as important as the size in determining the velocity of water required to lift it. In dealing with very fine particles the simpler process of sedimentation was to be preferred.

Prof. Porter, the President of the Faraday Society, in closing the discussion, referred to centrifuging as a means of grading fine powders, and commented on the relationship which Prof. Lowry had put forward between velocity and grain-size. He also referred to the utility of the discussion and especially to the value of bringing together workers from different fields, who could present information which, although well known to one section of individuals, might not be known at all to other groups represented at the meeting.

The International Petroleum Commission.

AT the ninth annual General Meeting of the Institution of Petroleum Technologists, held on March 14, Prof. J. S. S. Brame delivered his presidential address, taking for his subject the proposals for the re-establishment of the International Petroleum Commission. International Petroleum Congresses were held in 1900, 1904, and 1908, and committees were appointed to establish methods of testing products. Little was actually achieved, and in 1909 an International Petroleum Commission of wider scope was established. The organisation of an English National Section was referred to the Institution of Petroleum Technologists by Engler and Ubbelohde, but the intended meeting of the Commission at Bucharest in 1914 was prevented by the outbreak of war.

At the first annual meeting of the Petroleum Products section of the Société de Chimie Industrielle at Paris in 1921, M. Schmitz suggested the reconstitution and endowment of this Commission to be centred at the University of Strasburg. He spoke somewhat bitterly of the Americans "profiting by the general disorganisation to seek to abandon the analytical methods previously decided upon, in favour of their own."

Prof. Brame expressed grave doubts as to the wisdom and the justice of M. Schmitz's address. He could not believe that the largest oil-producing country, which had created such splendid organisations as the Bureau of Mines and the American Society for Testing Materials, was likely to depart from the methods of oil analysis it had elaborated and adopted. He outlined the development of these Institutions and the standard methods of petroleum testing they had recommended, and spoke of the cordial relationship between the Standardisation Committee of the Institution of Petroleum Technologists and these American organisations, from which collaboration he hoped would result an agreed system of nomenclature and specifications of the greatest mutual advantage. Such agreement he considered of much greater value to the two countries having by far the largest interests in petroleum than could be gained by the reinstitution of an International Petroleum Commission.

Facilities for Foreign Students in American Colleges and Universities.

THE Bureau of Education of the Government of the United States have issued under the above title, as Bulletin No. 39 of 1920, a revised and enlarged edition of a valuable handbook by Dr. S. P. Capen first published in 1915. It presents in a concise and readily intelligible form a comprehensive survey of a subject concerning which few people in this country have more than a very fragmentary knowledge. After a brief account of the organisation of education of all grades and a historical summary of the college and university systems, the Bulletin gives a description of the parts and working of the typical university and draws a comparison between American and other educational institutions. Next follow particulars of the cost of living and travel, athletics, clubs, etc., and lists of institutions of collegiate or professional grade located in the principal metropolitan centres of higher education, namely, New York, Chicago, Philadelphia, St. Louis, Boston, Baltimore, San Francisco, New Orleans, and Washington. Forty-five pages are devoted to a detailed definition of the requirements of the College Entrance Examination Board, an organisation formed by some 30 colleges together with the principal associations of colleges and secondary schools, which holds examinations in almost every State and in several foreign countries, including Canada, England, and France.

Colleges (and the collegiate, or undergraduate, divisions of universities) have, we are informed, come by common consent to express their entrance requirements in terms of "units," a unit representing "a year's study in any subject in a secondary school, constituting approximately a quarter of a full year's work. A four-year secondary school curriculum (the normal preliminary to admission to a college) should be regarded as representing not more than 16 units of work." Accordingly the definition of requirements includes not only examination syllabuses but also outlines of secondary school courses of study. Accounts of some approved methods of instruction and typical time-tables are added. As pointed out in the article on America in the Universities Year-book, 1922, "a peculiarity of the American system of grading, both in secondary and in higher institutions, is the weight attached to the length of time spent under instruction, a degree being attainable by gradual accumulation of a specified number of 'credits' (certificates of definite periods of time spent successfully under instruction) which thus largely replace the examinations used in other countries for testing the student's capacity at various intervals."

More than half of the Bulletin is devoted to descriptions of 74 universities, colleges, and technical and professional schools which have already been frequented by foreign students or which give courses likely to prove of special interest to such students. The descriptions deal with courses, degrees, equipment, expenses, strength of staffs, number of students, number of foreign students, and miscellaneous items of special interest to foreign students. There are also statistical tables for 1918 relating to State universities and certain agricultural and mechanical colleges, schools of mines, and other technological schools, and a list of medical colleges rated as Class A by the council on medical education of the American Medical Association. A few copies of the Bulletin are available at the Universities Bureau, 50 Russell Square, and can be obtained on payment of 1*s*. 3*d*. to cover the price (15 cents) and postage.

University and Educational Intelligence.

BIRMINGHAM.—The University has received from the Trustees of the James Watt Memorial Fund the sum of 5000*l*. towards the establishment of a Chair of Research in Mechanical Science to be known as "The James Watt Chair."

Mr. James Couper Brash has been appointed professor of anatomy, to fill the vacancy occasioned by the lamented death of Prof. Peter Thompson. Mr. Brash held the position of acting professor during the leave of absence granted to the late professor. The appointment of Mr. Cyril A. Raison as part-time assistant in anatomy has been confirmed by the Council.

CAMBRIDGE.—The family of the late Mr. J. M. Dodds have founded at Peterhouse a studentship to be known as the J. M. Dodds studentship for the promotion of advanced study or research in the subjects of mathematics or physics. The first election will be held in June 1923.

LONDON.—Application for grants from the Dixon Fund for assisting scientific investigations must be made before May 15 to the Academic Registrar, University of London, South Kensington, S.W.7.

Prof. J. A. Fleming has been compelled, on account of illness, to cancel all engagements for the present, and will consequently be unable to deliver the course of lectures on "Modern Improvements in Telephony" at University College which had been announced to begin on April 26. It is hoped that Prof. Fleming will be able to deliver the course in October.

MANCHESTER.—Prof. J. W. Smith has intimated his intention to resign, as from the end of the present session, the Chair of Systematic Surgery, which he has held since 1911. The following appointments have been made in the Faculty of Technology: Lecturers in Mechanical Engineering, R. M. Anderson, H. Threlfall; Lecturer in Spinning, J. Winterbottom; Demonstrators in Chemical Technology, W. H. Brindley, W. Hubball, W. H. Kelly, Esther Levin, and J. D. Mounfield; Demonstrator in Metallurgy, G. Mohn.

SHEFFIELD.—A course of five lectures on coal will be given in the Department of Applied Science on April 27 and successive Thursdays at 5·30 P.M. The first lecture, to be delivered by Dr. Marie Stopes, will deal with the palæobotanical aspects of the constitution of coal; the second, by Mr. F. S. Sinnatt, with the preparation of coal for the market; the third, by Dr. R. Lessing, with the carbonisation of coal; the fourth, by Mr. M. Wynter Blyth, with the manufacture of crude benzole; and the fifth, by Prof. J. W. Cobb, with the nitrogen in coal and its recovery as ammonia.

THE Education and the Parliamentary Committees of the British Science Guild have had under their careful consideration the recommendations of the Geddes Committee so far as these affect education. Their report, which has received the approval of the executive committee of the Guild, embodies certain proposals with the object of effecting reduction in expenditure where it can be shown to be without detriment to the legitimate purposes of educational expenditure. They desire to suggest one or two changes in such expenditure whereby economy in time and money can be achieved. It is essential that financial control shall be the duty of both State and local education authorities. The first consideration is, how much can be raised annually, both locally and Imperially, in respect of education and its ancillary needs, and next, how it can best be allocated in accordance with the legitimate claims of each department. The second essential is that the education committee to which the administration of education is delegated by the local authority shall be held responsible for the use of the funds. The present method of allotment of State moneys, namely 50 per cent. of the permitted local expenditure, is not peculiar to education but prevails in other State departments, and is under review with regard to its continuance. It is alleged that it multiplies unduly public officials, increases expense both of time and money, and that it is subversive of the principle of local control. The suggestion in the Geddes Committee's Report that the lower limit of compulsory age should be raised from five to six is commended, but with the proviso that it shall be accompanied by the institution of nursery schools for young children under the age of six years. A modification of the present scholarship system is suggested whereby only children of exceptional capacity, and whose parents cannot pay for their further education, shall be eligible for free places and for maintenance grants, available in schools of widely varying type. It is recommended that the practice of duplication of inspectorships should be abolished. One set of inspectors would be found quite efficient. If these reforms were carried out, much of the time now taken by unnecessary clerical work on the part of the highly paid staff of teachers and officials would be saved, and their efforts be devoted to more fruitful educational results.

Calendar of Industrial Pioneers.

April 13, 1742. John Lofting died.—Born in Holland about 1659, Lofting removed to London in 1688, where he became well known as a successful inventor and maker of fire-engines.

April 13, 1874. James Bogardus died.—An American inventor, Bogardus made improvements in clocks, constructed a delicate engraving machine, invented the dry gas meter, a deep-sea sounding machine, and a dynamometer, while his plan for manufacturing postage stamps was accepted by the British Government.

April 13, 1894. William Haywood died.—For forty-eight years Haywood was chief engineer to the Commissioners of Sewers in London, and he was also the constructor of the Holborn Viaduct. He introduced the use of asphalt for city roads.

April 15, 1908. J. Wigham Richardson died.—The founder of an important shipbuilding firm on the Tyne, Richardson contributed much to the advancement of the building of large mercantile vessels and served as President of the North-East Coast Institution of Shipbuilders and Engineers.

April 17, 1899. Sir James Wright died.—The successor of Thomas Lloyd as Engineer-in-Chief of the Navy, Wright held this position from 1872 to 1887. Trained at Dundee, he became an assistant in Woolwich Dockyard in 1845, and was transferred to the Admiralty two years later. He was intimately connected with the adoption of the compound engine, twin screws, forced draught, high pressures, and the triple expansion engine.

April 18, 1916. Sir John Durston died.—One of the few fellows of the Royal School of Naval Architecture and Marine Engineering, Durston entered the Royal Navy in 1866 as an assistant engineer and rose to be the Engineer-in-Chief. Taking office in 1889, at a time of great difficulty, Durston held office till 1907, and to him was mainly due the introduction into the Navy of the water-tube boiler and the Parsons steam turbine.

April 18, 1920. Rudolph Messel died.—Educated at the University of Tübingen, where he studied chemistry under Strecker, Messel after the Franco-Prussian War came to England, where he joined Squire. He worked out a method for the manufacture of fuming sulphuric acid, and with Squire erected important chemical works at Silvertown.

April 19, 1904. Sir Clement Le Neve Foster died.—From the Royal School of Mines Foster passed to the Mining Academy at Freiburg, and in 1860 joined the Geological Survey. He was an inspector of mines from 1872 to 1901, and in 1890 succeeded Warington Smyth as professor of mining in the Royal College of Science. His important work on "Ore and Stone Mining" appeared in 1894. In 1903 he was knighted.

April 19, 1914. Alfred Noble died.—After serving in the American Civil War, Noble studied civil engineering in the University of Michigan, and became an eminent constructor of canals, docks, and bridges. He was a member of various commissions appointed to report on the feasibility of a ship canal across the Isthmus of Panama, and he played an important part in solving some of the engineering problems connected with the Panama Canal. He served as President of the American Society of Civil Engineers, and in 1910 received the John Fritz medal for "notable achievements as a Civil Engineer."

E. C. S.

Societies and Academies.

London.

Royal Society, March 30.—Sir Charles Sherrington, president, in the chair.—The late W. G. **Ridewood**: Observations on the skull in fœtal specimens of whales of the genera Megaptera and Balænoptera. Five fœtal skulls were described. The presence of an interparietal bone in some whales, and the meeting of the parietals in a median suture in others, is of little use in taxonomy. Syncondyly is associated with suppression of the atlanto-epistropheal joint. There is no separate foramen for the hypoglossal nerve. The periotic bone shows no separate centres of ossification, but a diffuse endochondral granular deposit. The orbitosphenoid ossifies independently of the presphenoid. In whales there is no "external pterygoid plate" of alisphenoidal origin; the alisphenoid is the ossified ala temporalis. The growth of the malleus and of the tympanic bone, and the relations of the great bulla to the primary annulus tympanicus, were described.—W. L. **Balls**: Further observations on cell-wall structure as seen in cotton hairs. The daily growth rings consist of large numbers of fibrils, spirally arranged, with frequent reversals of the direction of the spirals. This arrangement is predetermined for the secondary cellulose of the growth rings by the initial pattern laid down in the primary wall. The individual fibrils have a cross-sectional area of the order of 0·05 square microns. Some of the evidence suggests stereo-isomerism in cellulose.—L. T. **Hogben** and F. R. **Winton**: The pigmentary effector system. I. Re-action of frog's melanophores to pituitary extracts. The posterior lobe of the pituitary gland contains a specific stimulant which, if injected into the frog, brings about a condition of general and complete expansion of the dermal melanophores. A minute dose induces a darkening of the skin readily visible to the naked eye. The pituitary melanophore stimulant is not destroyed by pepsin or boiling. It is rapidly destroyed by trypsin but not so quickly by acid hydrolysis. After cocaine, curare, atropine and apocodeine it still evokes its characteristic response, and therefore acts directly upon the melanophores. The results confirm the endocrine significance of the condition of general pigmental contraction found by Allen and others to follow removal of the pituitary gland in tadpoles.—Agnes **Arber**: On the development and morphology of the leaves of palms. The leaf-stalk is the basal or proximal region of the true petiole while the "fan" or "feather" limb is a modification of the distal region of the true petiole. The complex plication of the limb arises through the development of a series of invaginations penetrating the leaf-stalk tissue between the bundles. The "ligule" and "dorsal scale" of the fan-palms represent adaxial and abaxial distal margins of the uninvaginated proximal region of the petiole. The palm leaf, as a whole, is a petiolar phyllode with a pseudo-lamina.—H. E. **Roaf**: The acidity of muscle during maintained contraction. Records of electrical changes by a manganese dioxide electrode in combination with a calomel electrode show that: (*a*) In a veratrinised muscle the acidity remains as well as the tension. (*b*) In decerebrate rigidity reflex inhibition is accompanied by a decrease in acidity. Thus acidity and tension are related and a single mechanism is sufficient to account for both tetanus and tone.

Geological Society, March 22.—Prof. A. C. Seward, president, in the chair.—Sir Charles J. **Holmes**: Leonardo da Vinci as a geologist. Leonardo was the

first to have a large and accurate conception of the causes underlying the physical configuration of the earth. His studies of aqueous erosion, the formation of alluvial plains, the process of fossilisation, and the nature of stratification, led him to a logical conviction of the immensity of geological time, far in advance of the dogmatic thought of his age, and exposed himself to the charge of atheism. Caution compelled him to work in isolation, and to keep his results concealed. He had no scientific instruments, no correspondents to furnish him with observations on geological conditions elsewhere; yet his grasp of the physical history of the portions of Italy which he had visited was sound, and entirely in accord with modern knowledge. Leonardo left a record of his discoveries in his paintings, generally in the backgrounds. There are found pictures of the primeval world as he imagined it, when seas and lakes ran up to the foot of the mountains, to be slowly displaced and silted up by the detritus which the rain carried down from the summits.

Brussels.

Royal Academy of Belgium, March 4.—M. A. Lameere in the chair.—C. **Servais**: The geometry of the tetrahedron, Pt. 4. The cubic surface of Cayley.—P. **Martens**: The cycle of the somatic chromosome in *Paris quadrifolia*.

Diary of Societies.

FRIDAY, April 14.

Malacological Society (at Linnean Society).

WEDNESDAY, April 19.

Royal Meteorological Society, at 5.—W. T. Russell: The Relationship between Rainfall and Temperature as shown by the Correlation Coefficient.—R. A. Fisher: The Correlation of Weekly Rainfall.—Prof. S. Chapman and Miss E. Falshaw: The Lunar Atmospheric Tide at Aberdeen, 1869–1919.

Royal Microscopical Society, at 8.—C. Beck: The Photometry of a Bull's-Eye Lens for Illuminating Microscopic Objects.—Dr. S. C. Harland and J. H. Denham: The Use of the Microscope in Cotton Research.—Dr. R. S. Ludford: The Morphology and Physiology of the Nucleolus.—H. Sutcliffe: The Use of the Microscope in the Rubber Industry.

THURSDAY, April 20.

London Mathematical Society (at Royal Astronomical Society), at 5.

Institution of Mining and Metallurgy (at Geological Society), at 5.30.

Child-Study Society (at Royal Sanitary Institute), at 6.

Institute of Metals (London Section) (Annual General Meeting at Shaftesbury Hotel, Great St. Andrew Street, W.C.1), at 8.—H. Moore: The Ball Hardness Test.

FRIDAY, April 21.

Institute of Transport (at Royal Society of Arts), at 5.—J. K. Bruce: The Operation of a Large Tramway Undertaking, with reference to Capacity and Cost under given Conditions.

British Dyestuffs Industry.

THOSE who scrutinise with anxious attention the progress of the British dyestuffs industry are aware that the stage now reached is one surrounded by dangers of a character more economic than technical. The Dyestuffs (Importation) Act has been in operation during fifteen months, and at the outset of this period two main factors contributed to smooth administration. As a consequence of the Sankey judgment, this country had been flooded with German dyes in quantity and variety amply sufficient to supply the normal needs of one year's good trade; concurrently, every branch of industry was facing an abnormal depression, which reflected itself in a greatly diminished consumption of dyestuffs. It followed that the principal problems arising in regard to licensing imports were questions affecting identity or equivalence of the domestic dyes when competing with foreign products.

The period under review has been one of steady progress by the British factories, and an opportunity to visualise their achievement was offered lately by an imposing exhibition of synthetic colouring matters at the British Industries Fair. Still more recently, Brig.-Gen. Sir William Alexander, Chairman of the British Dyestuffs Corporation, invited a large gathering of press representatives to review the circumstances in which the renascence of this industry took place, and to apprehend the nationally fundamental need of maintaining it. There is grave public danger in the present risk that, as the connection between dyestuffs and explosives recedes into the background of the public mind, the more permanently important features of this industry will sink into oblivion. Failure to realise how closely the chemical industry is linked with the general manufacturing activities of the country springs from the apathy with which chemistry, particularly the organic branch, has been regarded in Great Britain, and Sir William Alexander has rendered a public service in emphasising the fact that research in the dyestuff industry creates and maintains a very highly trained body of organic chemists who, in an emergency, are qualified to apply themselves to technical national problems, whether these relate to peace or war.

This admonition is a timely one, because a variety of circumstances indicate growth of opposition to the principle of the Dyestuffs (Importation) Act. At the moment, although great strides have been made by the research departments of the British factories towards improving the quality and diminishing the cost of their colours, prices are still in many cases higher than can be viewed with equanimity by the dyer or calico-printer, and advantage is being taken of this drawback by those who, from motives of gain, or in disregard of national interests, seek the repeal of the Act. Owing to countless variations of detail in the application of dyestuffs to textiles, it is difficult to secure trustworthy information respecting the percentage of cost borne by a colouring matter in the finished product; in some cases it is trifling, in others it may be substantial, and in the general scramble to reduce cost of production, it is natural for those colour-users whose range of vision is not wide to pounce upon the dye-costs and demand relief. Meanwhile, the opportunity now in the hands of German factories owing to currency depreciation is one which they have not been slow to use, but it would be foolish to imagine that any mercy will be shown by Germany to British colour-users if once the domestic industry is allowed to perish.

Happily there are colour-users who look beyond the needs of the moment, and to such it is evident that the effort now being made to shatter the industry in adolescence must, in the interest of the whole community, be faced and overcome. If this country is not allowed to establish a dye-making industry, incalculable damage will ultimately accrue to the textile trade. In the first place, the dyer will suffer in becoming a spoon-fed vassal of the German factories; he will grow less and less capable of exercising his craft intelligently, and of devising novel applications to textile fabrics. This will diminish the attraction which British products offer to foreign markets, and in that degree curtail the operations of the textile manufacturer, who will be further handicapped by exorbitant prices for German dyes. Finally, if this, the principal industrial incentive to the pursuit of applied organic chemistry be permitted to languish, this country deliberately excludes itself from the immediate benefits,

and the potential profits, of all future revolutionary discoveries comparable with that which, in 1856, led to the displacement of natural colouring matters by the products of coal-tar chemistry.

Sexual Life and Marriage among Primitive Mankind.

The History of Human Marriage. By Prof. E. Westermarck. Fifth edition, rewritten. Vol. 1, pp. xxiv + 571. Vol. 2, pp. xii + 595. Vol. 3, pp. viii + 587. (London: Macmillan and Co., Ltd., 1921.) Three Volumes. 84*s*. net.

COMPARATIVE sociology, in many of its branches, started with very simple and homely concepts, and now, after a career of imaginative and somewhat sensational spinning of hypotheses, we find it returning in its latest developments to the position of common sense. The subject of family and marriage, of their origins and evolution, epitomises such a typical course of sociological speculation. In the views about the human family, there was first the uncritical assumption that the family was the nucleus of human society; that monogamous marriage has been the prototype of all varieties of sex union; that law, authority and government are all derived from patriarchal power; that the State, the Tribe, economic co-operation and all other forms of social association have gradually grown out of the small group of blood relatives, issued from one married couple, and governed by the father. This theory satisfied common sense, supplied an easily imaginable course of natural development, and was in agreement with all the unquestioned authorities, from the Bible to Aristotle.

But some sixty years ago, among the many revolutions in scientific thinking and method, the family theory of society seemed to have received its death-blow. The independent researches of Bachofen, Morgan and MacLennan seemed to prove beyond doubt, by the study of survivals and ethnographic phenomena, by methods of linguistics, comparative study and antiquarian reconstruction, that the whole conception of primeval monogamous marriage and early human family was nothing but a myth. Primitive humanity, they said, lived in loosely organised hordes, in which an almost complete lack of sexual regulation, a state of promiscuity, was the usage and law. This, the authors of this school concluded, can be seen from many survivals, from the analysis of classificatory systems of relationship, and from the prevalence of matrilineal kinship and matriarchate. Thus, instead of the primitive family we have a horde; instead of marriage, promiscuity; instead of paternal right, the sole influence of the mother and of her relatives over the children. Some of the leaders of this school constructed a number of successive stages of sexual evolution through which humanity was supposed to have passed. Starting from promiscuity, mankind went through group marriage, then the so-called consanguineous family or Punalua, then polygamy, till, in the highest civilisations, monogamous marriage was reached as the final product of development. Under this scheme of speculations, the history of human marriage reads like a sensational and somewhat scandalous novel, starting from a confused but interesting initial tangle, redeeming its unseemly course by a moral *dénouement*, and leading, as all proper novels should, to marriage, in which "they lived happily ever after."

After the first triumphs of this theory were over, there came, however, a reaction. The earliest and most important criticism of these theories arose out of the very effort to maintain them.

In the middle eighties of last century, a young and then inexperienced Finnish student of anthropology started to add his contribution to the views of Bachofen and Morgan. In the course of his work, however, the arguments for the new and then fashionable theories began to crumple in his hands, and indeed to turn into the very opposite of their initial shape. These studies, in short, led to the first publication by Prof. Westermarck in 1891 of his "History of Human Marriage," in which the author maintained that monogamous marriage is a primeval human institution, and that it is rooted in the individual family; that matriarchate has not been a universal stage of human development; that group marriage never existed, still less promiscuity, and that the whole problem must be approached from the biological and psychological point of view, and though with an exhaustive, yet with a critical application of ethnological evidence. The book with its theories arrested at once the attention both of all the specialists and of a wider public, and it has survived these thirty years, to be reborn in 1922 in an amplified fifth edition of threefold the original size and manifold its original value. For since then Prof. Westermarck has developed not only his methods of inductive inference by writing another book of wider scope and at least equal importance, "Origin and Development of Moral Ideas," but he has also acquired a first-hand knowledge of savage races by years of intensive ethnographic field work in Morocco, work which has produced already numerous and most valuable records.

Where does the problem stand now? First of all, the contest is not ended yet, and divergencies of opinion obtain on some fundamental points, while controversy

has not lost much of its uncompromising tone. But the issues have narrowed down somewhat. There is no longer a question of accepting the naïve theory which regarded family as a kind of universal germ of all social evolution; nor, on the other hand, does any competent sociologist take very seriously the fifteen successive stages of promiscuity, group marriage, Punalua marriage, etc. Prof. Westermarck and his school do not maintain the rigidly patriarchal theory, and they are fully aware of the importance of matrilineal descent, of the maternal uncle's authority, and of the various kinship anomalies connected with matriliny. The classificatory terms of relationship are, moreover, not considered by Prof. Westermarck as mere terms of address, but as important indications of status.

The representatives of the opposite school had also to make some concessions, though rather reluctantly and grudgingly. Scarcely any one nowadays would be so irreverent towards our ape-like ancestors and ancestresses as to suspect them of living in a general state of promiscuity. But there is still a formidable list of names, among them some of the most eminent representatives of modern anthropology, quoted by Prof. Westermarck (vol. 1, p. 103 *n.*), who consider primitive promiscuity as "not improbable," "plausible," "by no means untenable," and use this hypothesis constantly as a skeleton-key to open all questions of sex. Group marriage is still, though somewhat faint-heartedly, affirmed to have existed, and even some savages are forced to live up to their evil reputation—in the speculations and bare assertions of some writers. The Punalua family leads an even more shadowy existence, merging into a combined polyandry and polygamy. The most tenacious survival of the Bachofen-Morgan-MacLennan theories seems to be the kinship terms, themselves a most fecund breeding-place for all kinds of survival theories.

Thus Prof. Westermarck in this new edition is not altogether relieved of the necessity of dealing with the hypothesis of promiscuity, and in chapters iii.-ix. he examines the various classes of evidence adduced in its favour. There is a number of statements affirming directly the existence of promiscuous conditions among this or that tribe or people. Some of them come from garrulous and credulous writers of antiquity and have to be discarded as pure fables; others, from modern travellers, equal them in untrustworthiness and futility. On this point no one will certainly controvert the author when he says "that it would be difficult to find a more untrustworthy collection of statements." The investigation then turns to that remarkable group of ethnological facts—*Jus Primae Noctis*, licence of festive and religious character, prenuptial and orgiastic sexual intercourse—in which the powerful instinct of sex, curbed and fettered by social regulations, takes, in its own time, revenge on man by dragging him down to the level of a beast. Prof. Westermarck fully admits the importance and extent of these phenomena; his survey indeed shows the extreme range and the often astounding perversity of these deviations. But he declines resolutely to see in any of these facts a survival of pristine promiscuity, for in all cases the facts reveal most powerful motive forces, and can be attributed to definite psychological and social causes. The theory of survival is moreover irreconcilable with the fact that we find side by side with licentious tribes, savages who maintain strict chastity; that some of the most primitive ones are virtuous, whilst the most luxuriant growth of licence is found in more advanced communities; that, finally, civilisation instead of abolishing these phenomena only modifies them.

The chapters on customary and regulated sexual licence are full of penetrating suggestions, and the facts, skilfully marshalled, are made to speak for themselves, and will supply a lasting compendium for students of sexual psychology. But what appears most valuable in this, not less than in other parts of the work, are the methods and implications of the argument. Prof. Westermarck has an abhorrence of the now fashionable tendency of explaining the whole by its part, the essential by the irrelevant, the known by the unknown. He refuses to construct out of meagre and insufficient evidence a vast, hypothetical building, through the narrow windows of which we would have to gaze upon reality, and see only as much of it as they allow. The obvious, common-sense and essentially scientific way of proceeding is to get firm hold of the fundamental aspects of human nature—in this case the psychology of sex, the laws of primitive human grouping, the typical beliefs and sentiments of savage people—and, in the light of this, to analyse each fact as we meet it. But to construct the unverifiable hypotheses of primitive promiscuity and interpret facts in terms of figments is, as Prof. Westermarck shows, a method which leads nowhere and lures us from the true scientific path.

Some of the other chapters of Prof. Westermarck's book give us another approach to the psychology of sex and to the theory of human marriage. Sex is a most powerful instinct—one of the modern schools of psychology tries to derive from it almost all mental process and sociological crystallisation. However this may be, there is no doubt that masculine jealousy (chap. ix.), sexual modesty (chap. xii.), female coyness (chap. xiv.), the mechanism of sexual attraction (chap. xv. and xvi.) and of courtship (chap. xiii.)—all these forces and conditions made it necessary that even in the most primitive human aggregates there should

exist powerful means of regulating, suppressing and directing this instinct. There is no doubt that all the psychological forces of human sexual passion, as well as the conditions of primitive life, must have tended to produce a primeval habit of individual pairing. We have to imagine a man and a woman forming more or less permanent unions which lasted until well after the birth of the offspring. This, Prof. Westermarck develops in the first chapter of his work. A union between man and wife, based on personal affection springing out of sexual attachment, based on economic conditions, on mutual services, but above all on a common relation to the children, such a union is the origin of the human family. This primeval habit, according to the "tendency of habits to become rules of conduct," develops with time into the institution of family and marriage, and "marriage is rooted in the family, rather than the family in marriage."

Marriage, indeed, right through the book, is conceived in the correct sociological manner, that is, as an institution based on complex social conditions. The greatest mistake of the writers of the opposing school—a mistake which, I think, they have not corrected even in the most recent publications—is their identification of marriage with sexual appropriation. Nor is this pitfall easy to avoid. For us, in our own society, the exclusiveness of sexual rights is the very essence of marriage. Hence we think of marriage in terms of individual sexual appropriation, and project this concept into native societies. When we find, therefore, groups of people living in sexual communism, as undoubtedly happens among a few tribes within a limited compass, we have a tendency at once to jump to conclusions about "group marriage."

To the majority of savages, however, sexual appropriation is by no means the main aspect of marriage. To take one example, there are the Trobriand Islanders, studied by the present writer, who live in the greatest sexual laxity, are matrilineal, and possess an institution which is probably the nearest approach to "group marriage" that exists or could ever have existed. Indeed, it resembles it much more, I think, than does the celebrated Pirrauru of the Dieri in Central Australia. These natives satisfy their sexual inclinations through all forms of licence, regulated and irregular, and then settle down to marry, decidedly not only or even mainly to possess a partner in sex, but chiefly out of personal attachment, in order to set up a household with its economic advantages, and last, not least, to rear children. The institution of individual marriage and family among them is based on several other foundations besides sex, though sex—naturally—enters into it.

Space does not allow me to follow Prof. Westermarck into his dialectic contests with the most eminent of his contemporaries—with Sir James Frazer and Dr. Rivers about the kinship terms (chap. vi.); with Sir James Frazer and Mr. Hartland on matriliny (chap. viii.); and with all of them, as well as Spencer and Gillen, on group marriage (chap. xxvi.). In all these arguments we find the same extensive use of ethnological material, the same breadth of view and moderation of doctrine, above all, the same sound method of explaining the detail by its *whole*, the superstructure by its foundation. In the treatment of kinship and matriliny, too little concession is perhaps made to the important theories of Sir James Frazer and Mr. Hartland, whose views, unquestionably correct, that ignorance of paternity is universal and primitive among savages, Prof. Westermarck cannot accept. Nor can he see perhaps sufficiently clearly the enormous influence of this savage ignorance on primitive ideas of kinship. As Sir James Frazer says:

"Fatherhood to a Central Australian savage is a very different thing from fatherhood to a civilized European. To the European father it means that he has begotten a child on a woman; to the Central Australian father it means that the child is the offspring of a woman with whom he has a right to cohabit. . . . To the European mind the tie between a father and his child is physical; to the Central Australian it is social" ("Totemism and Exogamy," i. p. 236). The distinction between a physiological and a social conception of kinship is indeed essential. But, on the whole, Prof. Westermarck's views do not diverge so much from those of Frazer's, who, on the other hand, occupies a moderate position among the supporters of the opposite theories.

Prof. Westermarck's explanation of exogamy, and of the prohibition of incest—which I think will come to be considered as a model of sociological construction, and which remarkably enough seems to find favour with no one—can only be mentioned here. The excellent chapters on marriage rites (chaps. xxiv.-xxvi.); the analysis of what could be called the numeric varieties of marriage, monogamy and polygamy (chaps. xxvii.-xxviii.); polyandry (xxix.-xxx.); duration of marriage (xxxii.-xxxiii.), stand somewhat apart from the main argument of the book. Each division is a monograph, a *Corpus Inscriptionum Matrimonialium*, a treatise in itself.

The book is and will remain an inexhaustible fount of information, a lasting contribution towards the clearing up of some of the most obscure aspects of human evolution, and it marks an epoch in the development of sociological method and reasoning.

B. Malinowski.

Some Chemical Treatises.

(1) *Fundamental Principles of Organic Chemistry.* By Prof. C. Moureu. Authorised Translation from the Sixth French Edition by W. T. K. Braunholtz. Pp. xviii+399. (London: G. Bell and Sons, Ltd., 1921.) 12*s.* 6*d.* net.

(2) *A Text-book of Inorganic Chemistry.* Edited by Dr. J. N. Friend. Vol. 9, part 2, *Iron and its Compounds.* By Dr. J. N. Friend. (Griffin's Scientific Text-books.) Pp. xxv+265. (London: Charles Griffin and Co., Ltd., 1921.) 18*s.*

(3) *A Dictionary of Chemical Solubilities. Inorganic.* First edition by Dr. A. M. Comey. Second edition, enlarged and revised, by Dr. A. M. Comey and Prof. Dorothy A. Hahn. Pp. xviii+1141. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1921.) 72*s.* net.

(1) THE wealth of material comprehended by organic chemistry constitutes a very real and formidable difficulty to the instructor in that branch of science. It is calculated that up to the present time more than two hundred thousand organic substances have been discovered and described, and the number is being steadily added to week after week. It is obviously impossible for any lecturer on the subject to deal with more than a very small fraction of this *materia chemica.* Nor is there any reason why he should. Fifty or sixty years ago organic chemistry was scarcely taught in our universities, and, even when taught, was treated in a lifeless, unsystematic manner. Students, far from being attracted towards it, were frankly bored by the uninteresting recapitulation of empirical facts, methods of preparation, and physical properties, which usually made up the substance of the teacher's prelections. All this, however, is now changed. The enormous accretion of fact has been brought under law and order. The whole has been collated, and, for the most part, reduced to fundamental principles. The view of the village is no longer obscured by the houses.

It is with these fundamental principles alone, based upon the co-ordination of facts, or groups of facts, that the teacher of organic chemistry to-day can concern himself, if he would seek to convey any adequate conception of the field of study occupied by that department of science. In the hands of a capable, well-informed man, gifted with philosophic insight and endowed with the faculty of exposition, tuition in organic chemistry can be made a most fascinating occupation. To supplement the teacher's work in the lecture-room, however, the students should be provided with a well-ordered text-book, dealing with the principles concerned. Such a book is that under review. In its original form it has already been noticed in these columns. Since that time it has gone through many editions, and has found its way beyond French university circles. The sixth French edition has now been translated into English by Mr. Walter T. K. Braunholtz, and appears with an introduction from Prof. Sir William J. Pope, of the University of Cambridge.

We heartily commend Prof. Moureu's book to all—both teachers and taught—to whom the philosophic aspects of organic chemistry appeal. No more interesting work on the subject has appeared within recent years. It is written with that clarity, logical sense, faculty of arrangement, and sense of proportion which are such striking characteristics of French scientific literature. We trust that in its English dress it will have a reception commensurate with its great merits.

(2) As was mentioned in a former notice in NATURE of vol. 9 of Dr. Newton Friend's great work on inorganic chemistry, it has been found necessary to treat the subject of iron in a separate part of that volume, on account of the great importance of the metal and the voluminous literature which has grown round it. This has been found so great that it has been deemed desirable to subdivide the volume still further. The part now under review treats of the chemistry of iron and its compounds, its metallurgy being relegated to part 3, which is being dealt with by the editor in collaboration with Mr. W. H. Hatfield.

The general plan of part 2 is similar to that of the preceding volumes. It opens with an account of the early history of iron as a metal, beginning with the use of meteoric iron by prehistoric man, and of smelted iron by the Egyptians, Ethiopians, Assyrians, and Israelites. According to authorities quoted by Dr. Friend, India acquired her knowledge of iron from Babylon. The famous pillar at Delhi is far from being so old as is usually surmised. It dates back probably to about A.D. 300. Greece was the first country in Europe to use iron—probably about 1400 B.C. It was known in Britain about a century before the Roman invasion, when, as mentioned by Cæsar, it was used in the form of bars for currency. Specimens of these bars are in the British Museum and in the Worcester Museum. Chap. 2 is concerned with the mineralogy of iron, and gives an account of its ores and other ferruginous minerals, many of which, of course, are of no importance as sources of the metal. It is noteworthy that the mean percentages of ferrous and ferric oxides contained in American igneous rocks are considerably less than in similar British rocks. Chap. 3 treats of the preparation and properties of pure iron, the passivity of iron, its action as a catalyst, etc. A short section on its atomic weight is contributed by Mr.

Little. The final value 55·84 is sufficiently far from a whole number to suggest the existence of isotopes, for there is every reason to believe that this value is well established. In view of Dr. Aston's work, and the resuscitation of Prout's hypothesis, it will be interesting to learn how the difference from the integer is to be accounted for. Chap. 4 deals with the important subject of the corrosion of iron, of which the editor has made a special study. It is, however, remarkable, in spite of the large amount of work which has already been done on this subject, how much remains to be ascertained. The remaining chapters, five in number, deal with the general properties of iron salts, of its compounds with hydrogen and the halogens, and with the elements of Groups VI., V., IV., and III. of the Periodic Table. The whole concludes with a chapter on the detection and estimation of iron.

As in the case of the entire work, a special feature is a wealth of bibliographical reference. Practically every statement can be verified by reference to the original source of information. This, of course, adds greatly to the value of the treatise as a compendium, but it is naturally not of much service to the student without access to a well-found library. There is probably no single library in London in which all the books thus referred to could be found.

A new feature in the work is the inclusion of a table giving a list of important journals and periodicals dealing with chemical matters, with the dates of issue of their several volumes, from the year 1800 down to 1919. It was compiled by Mr. Clifford, the librarian of the Chemical Society, and occupies some eight pages of the book. Its value to the book itself is not very apparent, since the date of publication in the case of any particular reference is invariably given in the footnote. The table has no special appropriateness to the volume under review; its proper place would be either at the beginning or the end of the completed work.

(3) The "Dictionary of Chemical Solubilities," by Drs. A. M. Comey and Dorothy A. Hahn, is a revised and enlarged edition of a work by the first-named author which appeared in 1895, and which, in its turn, followed the well-known "Dictionary of Solubilities" compiled in 1864 by Prof. F. H. Storer on a plan indicated so far back as 1731 by Peter Shaw. Storer's book is long since out of print, and no attempt has been made to bring it up to date and to reissue it. During the quarter of a century which has elapsed since the first edition of Dr. Comey's work a large amount of additional matter relating to the solubilities of inorganic substances, with which the book is alone concerned, has made its appearance. This has been carefully brought together by Dr. Dorothy A. Hahn, of Mount Holyoke College, and forms the material upon which the present edition is based. It constitutes a volume of 1140 closely printed pages, and its subject-matter has been brought down to 1916. Its printing and publication have been delayed by circumstances arising out of the war.

In a work of this kind easy reference is of primary importance, and opinions may differ as to the best arrangement to adopt. The one used is practically alphabetical, but it will be obvious that such a scheme leads to occasional anomalies, which could be obviated only by elaborate cross-referencing, thereby adding considerably to the bulk of the volume. In the case of discrepant statements by different observers, no attempt at a critical selection has been made, which we think detracts from the value and authority of the work. A careful examination of the original papers and of the methods and apparatus employed would have enabled a satisfactory judgment to be reached, and thereby obviated much unnecessary printing. Methods of determining the solubilities of gases, for example, have been improved greatly since Bunsen's time, and many of his estimations have been superseded by more accurate observations. It serves no useful purpose to retain them, and indeed only confuses the searcher, who is not in a position to discriminate between the several observers. The compilers may rightly say they have done their best to deal with the enormous mass of material they have collected, but they can scarcely have escaped the conviction that much of the numerical data rests upon a very insecure experimental basis. The fact is, it is only within quite recent times that methods of estimating solubilities have reached the necessary precision, and that sources of error hitherto overlooked have been obviated.

In spite, however, of these difficulties and imperfections, the present work is the most comprehensive compilation on the subject which has yet appeared in any language, and a word of commendation is due to Dr. Hahn for the patience, care, and assiduity with which she has collected the vast amount of material with which she has had to deal.

Formal and Philosophical Aspects of Logic.

Logic. By W. E. Johnson. Part 1. Pp. xl+255. 16*s*. net. Part 2. Demonstrative Inference: Deductive and Inductive. Pp. xx+258. 14*s*. net. (Cambridge: At the University Press, 1921, 1922.)

A LOGICIAN is a person who takes infinite pains to solve problems which present no manner of difficulty to ordinary mortals. This may be, and no doubt is, because ordinary mortals live and die unconscious of

the inconsistencies of general theory. The logician is therefore of necessity a very serious person, and to suspect a twinkle in his eye when he is propounding his problem is to undermine his authority. But there is another reason why he must be serious. If he would make formal logic a distinctive science he must walk warily between the devil and the deep sea, for on the one hand he has to beware of falling into pure matters of grammar, the use and misuse of the parts of speech, and on the other hand he has to avoid the abyss of metaphysics. Indeed if one were to take a pencil and score through everything in a treatise on logic which really depends on an intelligent understanding and use of grammar and everything also which depends on a disputable metaphysical theory, it would be difficult to be sure that anything would remain. There used to be a subject, taught at universities, called rhetoric, and many chairs of it still survive, but it would puzzle any one now to say definitely what a professor of rhetoric is expected to teach. It looks as though logic may some day and very soon be in a similar case.

Two parts of Mr. Johnson's logic are yet to come. The two parts before us are exceedingly well written. Every sentence is a model of clearness and lucidity. However puzzled the reader may be when he discovers the sort of problems he is invited to discuss, if he yields to the spell and plays the game, he will find a certain philosophical interest which will engage his attention throughout.

The influence of "Principia Mathematica" is very much in evidence; probably without that work few of the problems here dealt with would have had any *raison d'être*, even if they had been discovered to exist. Thus Mr. Johnson makes a very important point of a division he proposes between propositions, verbally identical, into primary and secondary. Truth and falsity, he tells us, can be predicated of propositions in quite different senses according as they are one or the other. "Some fairies are malevolent" if it is a primary proposition is necessarily false because fairies do not exist. But if it applies to "descriptions" of fairies then, as descriptions exist, it is true, and it is a secondary proposition. Similarly, in the chapter on negation we are asked to consider propositions such as these opposites. "An integer between 3 and 4 is prime" and "An integer between 3 and 4 is composite." Here we are told that though one is contradictory of the other, neither is true because both have a non-existent subject. This is in keeping with the endless interest Mr. Russell discovered in the question of the truth or falsity of the proposition "The present King of France is bald." All one can say is that if any nonsensical content becomes a proposition once it is invested with the propositional form, then logic had better be abandoned to those for whom games are the serious business of life.

The author's main purpose, however, seems to be a more exact classification and an improved terminology. He thinks the serious objection urged against the correspondence theory of truth can be got rid of by substituting the terms "accordance" and "discordance" for correspondence and non-correspondence. We may admit that the new terms are in a sense non-committal, but is that a gain? Another proposal is concerned with the subject of Modality. It is to substitute "certified and uncertified," for the term problematic, and to distinguish the certified into formally certified and experientially certified, apparently in order to have technical terms in logic for the old philosophical distinction between truths of reason and matters of fact. Also for "necessary" he would substitute two pairs of terms, nomic and contingent, and, epistemic and constitutive. The peculiar character of proper names he proposes to designate by the term "ostensive." In all this we seem to be hearing the echo of Mr. Russell's complaint that we shall never make progress in science until we construct and use a scientific language.

Perhaps the most novel thing in the logical theory expounded in Part 1 is the Paradoxes of Implication. The "typical paradox" is certainly not what we ordinarily designate by that term, and the author is aware that his use requires justification. A paradox in the ordinary meaning is the affirmation of a proposition the actual terms of which include its negation, as for example, "Whoso loses his life shall save it." The essence of the paradox is that despite its apparent contradiction in form it contains defensible philosophic truth. The logical paradox here discussed is very different. You may be led by implication (p implies q) technically correct, to the form "if p then q" where p may stand for the proposition $2+3=7$ and q for the proposition "it will rain to-morrow," then you have the paradox. At this point no doubt the ordinary person would lose interest, but if you are a logician it is here the problem becomes engrossing.

One very interesting discussion, also in Part 1, is the famous Leibnizian principle of "the identity of indiscernibles." No one can fail to see that metaphysically the principle is an essential part of the concept of substance, yet logically there seems no way of keeping this in view, and the author reaches the conclusion—which is quite correct on his principles—that it seems to him in any case to have no logical justification whatever.

In Part 2 there is a distinct increase in the philosophical interest. The difference between the aspect of a problem to the philosopher and to the logician

becomes more marked, and the author is sometimes at pains to show that the doctrine he is discussing has reference purely to formal logic. The subjects dealt with are of the first importance. For example, the relation of logic to mathematics is discussed with very penetrating criticism, and Mr. Johnson finds that he differs from Mr. Russell on the fundamental concept of this relation. The mathematical function is for Mr. Russell a description derivable from the propositional function of logic, whereas Mr. Johnson argues that the propositional function of logic is nothing but a particular case of the mathematical. In discussing functional deduction generally Mr. Johnson says "the essential purpose of symbolism is to economise the exercise of thought; and thus symbolic methods are worse than useless in studying the philosophy of symbolism or of mathematics in particular."

There are many new distinctions discovered and new terms proposed. In particular we are to distinguish two direct principles of inference, the applicative and the implicative, each with a counter principle; we are to add to the distinctions of magnitudes as extensive and intensive an intermediate form termed distensive; and, more important still, we are to distinguish between the question of the absoluteness or relativity of space and time and the question of their substantival or adjectival nature. But perhaps the most astonishing distinction of all (is it a new discovery?) is that of the syllogism and the antilogism. The antilogism like the syllogism has its four modes A E I O, and, in the illustration given, simply by altering the mode we can present the argument for new realism, the argument for Hume's scepticism, or the argument for Kant's formalism. Verily formal logic may be in the way of becoming a formidable weapon in the hands of a philosophical controversialist.

Terrestrial Magnetism in the Antarctic.

British ("Terra Nova") Antarctic Expedition, 1910–1913: *Terrestrial Magnetism.* By Dr. C. Chree. Pp. xii + 548 + 60 plates. (London: Harrison and Sons, Ltd., 1921.)

BOTH of Captain Scott's Antarctic expeditions included observations of the earth's magnetism in their programme of scientific work, and the experience gained in the first was turned to good use in the second. The two magnetic observers were Dr. G. C. Simpson and Mr. C. S. Wright, to whom is due the credit for the fine work done at the base station. A noteworthy improvement was made by Dr. Simpson in the method of time-marking on the magnetograph sheets, which has since been adopted in some regular magnetic observatories. The magnetographs were in operation for nearly two years (February 1911 to November 1912); at the beginning of the second year Dr. Simpson was recalled to his official duties in India. Besides the continuous record of the three magnetic elements at Cape Evans, a considerable number of absolute measurements were made by the naval officers of the expedition, both in the "field" (principally at Cape Adare) and at sea.

The important task of preparing a report describing and discussing all these observations was entrusted, as in the case of the former expedition, to Dr. Chree. This report has just been issued, in the form of a large quarto volume, prepared and published at the cost of the fund raised by public subscription in memory of Captain Scott and his companions. Apart from the observations taken by the naval officers, which were mainly reduced by themselves, not only the discussion but also the reduction of the observations has been executed by or under the supervision of Dr. Chree; the measurement of the magnetograph curves, the reduction of the measurements, and the discussion of the important but somewhat tedious instrumental questions which arise, involve an amount of labour which can be but little appreciated by those unfamiliar with the subject. Of the 548 pages of letterpress, about one hundred are devoted to the tables, giving hourly values of the three magnetic elements, while about one-quarter of the volume is occupied by a valuable set of plates, mainly reproducing actual magnetograph records, from the Antarctic or elsewhere.

Following out his characteristic plan, Dr. Chree has kept strictly to the comparison and discussion of facts as facts; the echoes of theoretical controversy can be at most remotely perceived, and speculations as to the cause of the phenomena reviewed with such painstaking care are expressly deprecated by the author. Whether or not it is best at all times to restrict the discussion within these severe limits of certainty, few can disagree with the adoption of the course in preparing a report of this kind. In the spirit with which he has approached the task Dr. Chree has shown, not only his devotion to his chosen science, but also his personal appreciation of the work done by those who obtained the observations, or made the observations possible, in the inhospitable regions of the Antarctic.

The general plan of the volume is similar to that of the one dealing with the earlier expedition. The first six chapters describe the reductions which lead to the monthly mean values, non-cyclic changes, diurnal inequalities (with Fourier coefficients), daily range, and daily maxima and minima of the magnetic

elements; the rest of the discussion is on more individual and less standard lines. Dr. Chree devotes great attention to the important subject of the magnetic "activity"—its variations from day to day and from hour to hour, and its connection with other magnetic characteristics. He finds, for instance, that the remarkable differences existing between the Antarctic diurnal magnetic variations on quiet and on disturbed days are by no means merely proportionately intensified forms of the corresponding differences in temperate latitudes. Again, he investigates the tendency for a given state of magnetic activity to recur after twenty-seven days, a phenomenon long ago suggested by Broun and others, and independently established and brought into prominence more recently by Mr. Maunder. Dr. Chree uses his own admirable method based on daily character figures, and finds the tendency to be as clearly shown by the Antarctic as by the Kew records. The variation of the magnetic activity throughout the day, and even over short periods of an hour or so, has also been studied, the latter with the aid of the quick-speed records arranged to be taken simultaneously for "term hours" at the Antarctic and at many co-operating observatories. While these records have proved useful for the purpose named, Dr. Chree expresses doubt as to the desirability of including this arrangement in the programme of future polar expeditions.

Another subject discussed in much detail is magnetic disturbance of various kinds, including "sudden commencements," whether followed by a magnetic storm or not, large disturbances (studied from Antarctic and other records) and short-period disturbances. Some cases of the repetitions of disturbances at about the same hour on successive or adjacent days, such as were first noticed by Señor Capello in the Lisbon curves, were found in the Antarctic records, and are illustrated; it is to be regretted that the corresponding curves from other observatories were not obtained for these as well as for the larger disturbances discussed.

With the co-operation of Mr. C. S. Wright, an interesting chapter on the relation between auroræ and magnetic disturbance is included. In this chapter various definite numerical criteria are applied to test the view generally held that there is a close connection between the two phenomena. It is so difficult, on account of daylight, clouds and moonlight, to get records of auroræ at all comparable with the magnetic records in continuity or completeness that it requires some ingenuity to devise satisfactory numerical tests of the connection; Dr. Chree's tables succeed in confirming it, as they show that 41 per cent. of the "first-class" auroræ observed were associated with days of character-figure 2 (connoting a magnetically disturbed day), while no single aurora of the fourth class was so associated. It appears also that auroræ are probably rarely, if ever, totally absent, even at the times most quiet magnetically.

In order to utilise the results to the best advantage, Dr. Chree has not shrunk from entering upon enormous pieces of arithmetical computation, and the preparation of this report has been an enterprise which even those naturally most inclined towards numerical work might have shirked. The volume is necessarily restricted in its appeal, but magneticians will everywhere be grateful to Dr. Chree for the clear and accurate way in which he has ascertained and presented so many of the leading facts regarding the magnetic phenomena of the Antarctic.

The Analysis of Drugs.

The Chemistry and Analysis of Drugs and Medicines. By H. C. Fuller. Pp. ix+1072. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1920.) 55*s*. net.

THE number of drugs in use at the present day runs into thousands, and each of them is a component of one or more, often many more, "medicines." The materials used as drugs include such diverse products as plants the constituents of which are unknown, elementary substances such as colloidal copper and sulphur, and complex but well-defined compounds like "salvarsan." To prepare a comprehensive account of the analysis of drugs and medicines is therefore a difficult task, and one may doubt Mr. Fuller's wisdom, but not his courage, in tackling it.

He has produced a book which is inclusive rather than useful, and is unnecessarily large, owing to faults in the arrangement of matter and to needless repetition; thus the assay of the principal crude drugs is described in chap. 2, and drugs which contain alkaloids or glucosides are discussed again in the chapters devoted to these constituents, with the result that the determination of morphine in opium is dealt with on pp. 53-60, and a second set of processes for this operation is given on pp. 211-13, a cross-reference being provided in neither case.

Many authors inadvertently repeat themselves, but it must be unusual to find such a case as that of saligenin in this book, which is described twice, each time under a central heading in heavy type on the same page (553), and a third time on p. 787; the headings are different each time, viz. "ortho-oxybenzyl alcohol," "salicyl alcohol," and "saligenin," but a chemist, with his daily experience of vagaries in nomenclature, should be prepared for such pitfalls.

In writing names of chemicals the conventional plan of writing all the parts of a name together—*e.g.* "acetylbenzoylaconine"—is sometimes adopted; at other times they are separated by hyphens, as in "Para-hydroxy-phenyl-ethylamine"; but occasionally they are disconnected completely, as in "Benzoyl Ecgonin."

The defects of the book are, unfortunately, not limited to matters of arrangement and nomenclature. Thus the jaborandi alkaloids are wrongly grouped with the derivatives of pyridine, and the attributions in some other groups are doubtful, whilst the alkaloids of physostigma and anhalonium should not be described as "of unknown composition." In the section relating to solanaceous alkaloids the information is given that "hyoscin, which was formerly reported as a naturally occurring constituent of henbane, has now been virtually relegated to oblivion." In spite of this it is resurrected four pages further on in the curious form "Scopolamin, hydrobromate (Hyosin)," and is apparently reconsigned to oblivion, since it fails to appear in the section devoted to scopolamine. Though *Hyoscyamus muticus* has probably been the chief source of atropine for more than twenty years, the only reference to it is as follows: "*Hyoscyamus muticus* is often offered for import as true *H. niger*." Cotarnine, in spite of its importance in medicine, is not mentioned, though each of the minor alkaloids of opium has a paragraph to itself.

The resin of podophyllum is described as containing both podophyllotoxin and picropodophyllin, whereas only the former is present, the latter being an isomeride formed by the action of alkalis. The section on Indian gum may include all that is known about this commodity in the United States, but it is misleading as regards the sources and character of this gum as it appears in European markets. In the portion relating to resins no attempt is made to deal critically with the numerous doubtful data published regarding the chemistry of these products; thus the formula $C_{20}H_{40}O_2$ is assigned to abietic acid, though it is described as containing hydroxyl, and is presumably a hydroxy-acid, while sandaracolic acid is mentioned as a constituent of sandarac, though the author of this acid withdrew it years ago.

Enough has perhaps been said to show that Mr. Fuller's book should be used with discretion. As it deals with nearly everything, including chewing gum, that has been used or can be regarded as a drug, and gives references copiously, it is at least a useful guide to the all too voluminous literature on the analysis of these products, though even in this respect it would be improved if the index were more complete and always strictly alphabetical. T. A. H.

South African and Indian Floras.

(1) *An Introduction to the Flora of Natal and Zululand.* By Prof. J. W. Bews. Pp. vi+248. (Pietermaritzburg: City Printing Works; London: Wheldon and Wesley, Ltd., 1921.) 15*s*.

(2) *The Flora of the Nilgiri and Pulney Hill-Tops.* By Prof. P. F. Fyson. Vol. 3. Pp. xviii+581. (Madras: Government Press, 1920.) 15 rupees 6 annas.

(1) THE volume by Dr. Bews, who is professor of botany in the Natal University College, Pietermaritzburg, was written mainly for the purpose of assisting students of plant ecology and those engaged in botanical survey work in Natal. The flora of that country received for many years the devoted attention of the late Dr. J. Medley Wood, who published among several other works a "Handbook to the Flora of Natal" in 1907, and a "Revised List of the Flora of Natal" in 1908, to the latter of which two supplements were issued. The Handbook is now out of print, and the Revised List is not easy to procure, while both are incomplete. Dr. Bews's work, therefore, supplies a need and will be welcomed. It contains 478 species of flowering plants that are not included in Wood's Revised List. Like Wood's Handbook it gives keys to the families and genera, short descriptions of the former, and enumerations of the species, with a few words on their distribution and here and there a native name; the Cryptogams are excluded entirely.

A very important omission from both Dr. Wood's Handbook and Dr. Bews's Flora is some means for the identification of the species. We realise that to have provided keys to the species would have increased the size of the volumes very considerably, but it would have made them infinitely more useful. Some of the Natal genera are rich in species; Panicum has 35, Schizoglossum 41, Indigofera 44, Crassula 49, Senecio 84, while Helichrysum has as many as 92. With the best of keys it is difficult to determine the specific name of a plant belonging to any large genus, but Dr. Bews affords no help at all in the matter.

While Dr. Bews's book will no doubt be of service to those for whom it was chiefly intended, it does not go far enough. Much had already been done on the plants of Natal, and it might reasonably have been thought that the time had come when a work of more general usefulness could have been produced. It may be mentioned that Dr. Bews has arranged the families in his book according to Engler and Prantl's system, and that he has followed the practice observed by zoologists generally and by certain botanists of using a small initial letter for all specific names.

(2) Volumes 1 and 2 of Prof. Fyson's work were published in 1915, and were reviewed in Nature, vol. 96 (February 3, 1916), p. 615. These dealt with the flowering plants found above an elevation of 6500 feet around the hill-stations of Ootacamund, Kotagiri, and Kodaikanal. The present volume is supplementary, and includes the plants of the country around Coonoor above an elevation of 5000 feet.

The numerous outline drawings are an important feature in this volume as well as in the preceding; they certainly add considerably to the usefulness of the work, though, as they are full-page size, they have rendered it rather bulky and expensive. Notwithstanding that the text is in large, much leaded type it fills only 154 of the 599 pages in vol. 3; the other pages are used for the illustrations. These might have been reduced in size and the text might have been in smaller, less spaced type. By these means the matter in the three volumes could have been compressed into one. An admirable model might have been found in the late Colonel Sir Henry Collett's "Flora Simlensis." In Prof. Fyson's Flora we have another instance of the use of a small initial letter for all specific names. Whether this method of dealing with such names is advisable or not seems to be a matter of opinion; it has recently received some attention in the *Journal of Botany* (1921, pp. 159, 295-296).

Some additions and emendations in the volume under notice have been necessitated by the publication of Mr. J. S. Gamble's "Flora of the Presidency of Madras," of which the fourth part, carrying the work as far as the beginning of the Ebenaceae, appeared last August—too recent, therefore, for Prof. Fyson to have derived any assistance from it. He has been able to use Mr. Gamble's work only as far as the end of the Caprifoliaceae. It is probable, therefore, that the families from the Rubiaceae to the end will need some revisional treatment by Prof. Fyson, in order to bring his work into agreement with one that will be recognised for a long time to come as the authoritative Flora of Madras.

Science of Industrial Psychology

The Psychology of Industry. By Dr. J. Drever. Pp. xi+148. (London: Methuen and Co., Ltd., 1921.) 5*s*. net.

Industrial Fatigue and Efficiency. By Dr. H. M. Vernon. (Efficiency Books.) Pp. viii+264. (London: G. Routledge and Sons, Ltd., 1921.) 12*s*. 6*d*. net.

Two entirely different methods of approaching the science of industrial psychology are represented by the two volumes under notice. Dr. Drever's book is an attempt to cover the whole field of industrial psychology, and to accomplish such a task in a book of 148 pages must lay itself open to the charge of being somewhat superficial. He devotes a short chapter to each of the sub-divisions of the science, and quotes, in a not too critical spirit, certain well-known experiments which have been carried out. These examples are mostly taken from the writings of American efficiency engineers, and, interesting as they may be, they are not sufficient to form the foundation of a whole science. They must be submitted to a much more critical examination than Dr. Drever gives them if they are to form even part of the subject-matter of the science at all.

Dr. Vernon's book is of a very different type. Its object is not to write an introduction to a science which at present is so young that any such attempt must concern itself mostly with saying what can be accomplished, rather than what has already been done. His book is an attempt to deal with one aspect of the science and concerns itself more with facts than theories, and for this reason alone is far more scientific than Dr. Drever's book. In his preface Dr. Vernon says, "I have not attempted to discuss scientific management for I have no first-hand knowledge of it, and, moreover, the subject is so large a one that it needs independent treatment. For similar reasons I have not attempted to deal with Vocational Selection in industry." This passage is really the keynote to the whole book, for although the author quotes copiously from the works of other writers in the same field, yet his main argument depends on the first-hand information which he and his colleagues have collected from the various factories they have visited. Throughout the reader feels himself in touch with reality rather than in the somewhat theoretic atmosphere prevailing in Dr. Drever's book.

It is true that Dr. Drever's object is somewhat different from that of Dr. Vernon, for he tells us that the book was written primarily to awake interest in the ordinary man, and so help to spread knowledge of the service psychology can render to industry. Even so it may be doubted whether it is wise to spread knowledge in the way Dr. Drever has done. Those who are working in this field of applied science have two great practical difficulties with which to contend. One is the ignorance or antipathy of the ordinary man as to the possibility that physiology or psychology can render any appreciable services to the problems of industry, and the other is that he sometimes expects great results with comparatively little effort on the part of the scientific worker. Dr. Drever's book undoubtedly does much to remove the first difficulty, but in so doing it does a great deal to increase the second.

A book that devotes a chapter of fourteen pages to intelligence tests, and then gives in an appendix a foot-rule for intelligence testing, is bound to give the impression that any one with a certain degree of intelligence but without any special knowledge is in a position to apply such tests with fruitful results. Any such impression is erroneous in the extreme, and pays little respect to the psychologists who are experimenting in this field of research and are trying to overcome scientifically some of the difficulties inherent in the subject, which are either not mentioned or passed over so lightly by Dr. Drever.

The fundamental difference between these two books is that the author of one is mainly interested in industrial psychology from the point of view of the lecturer; while the main interest of the author of the other is that of the research worker. Industrial psychology has a long way to go before it can offer much scope for those who wish to lecture profitably about its principles, for most of these have to be discovered by the research worker and tested in various fields before they can claim to rank as truly scientific. It is because Dr. Vernon has attempted this that his book marks a definite advance in the science and should be read by all who are interested in the human side of industry either from the practical or the scientific point of view.

Glacial Climates.

Das Klima des Eiszeitalters. By Prof. Dr. R. Spitaler. Pp. iv + 138. (Prag: from the author, Smichow, 379. 1921.) 65K.

Dr Felix Oswald (Nature, vol. lxxv. p. 197) performed a remarkable feat when he printed his "Treatise on the Geology of Armenia" on a hand-press at Beeston in 1905. Prof. Rudolf Spitaler has reverted further, and has issued his work on glacial climates in a written script. The reproduction of this by lithography secures a uniformity that was not always possible among the ancients. He thus shows us a way out of the apparent *impasse* that has threatened scientific publication. The lodging in suitable libraries of, say, a hundred copies of a quarto memoir such as this would go far in the dissemination of ideas, and the process lends itself to tabular matter, freely used by Prof. Spitaler, and also to much delicacy of illustration. Authors in the days of imperial Rome were not dissatisfied with a manuscript mode of publication. The monumental "Naturalis Historia" of the elder Pliny, in thirty-seven books, gained a handsome circulation, and the author was engaged on a supplement—how well we know those supplements!—in the tragic year of 79. The genial Martial directs a would-be borrower to the shop of Attractus opposite Cæsar's forum, in the certainty that a copy of his latest poems could be bought there for five denarii. Allowing for the exchange, Prof. Spitaler asks little more, and we must remember that Roman publishers had the advantage of slave-labour.

In the beautiful script of his amanuensis, Prof. Spitaler supports the astronomical explanation of the climatic changes that produce or abrogate an ice-age. He divides the globe into zones of latitude, and shows how each would be affected by the variation of the perihelion position of the earth, combined with variation in the obliquity of the ecliptic. He lays stress on the distribution of land and water within the zones; climate is greatly affected by "continentality" and "oceanity." This, however (p. 29), does not account for the higher average temperature in January as against July at the equator, which is attributable to the occurrence of perihelion when winter reigns in the northern hemisphere.

A maximum excentricity of the orbit and a high obliquity of the ecliptic provide extreme conditions and promote glaciation; but Prof. Spitaler contends that even in these circumstances there need not be a reversal of the climate of each hemisphere every 10,500 years. He urges (p. 111) that a glacial climate, when promoted in the north, may affect the equator and still more the south, so that simultaneous glaciation over the whole earth, as postulated by A. Penck, is possible. Cool summers and mild winters (p. 94) favour snowfall, while hot summers and very cold winters are unfavourable. The maximum of the last warm period for the northern hemisphere (p. 57), when the summer took place in perihelion, is held to have occurred about 8500 years ago, an epoch that coincides presumably with the rapid melting back of the northern ice. The author (p. 131) looks forward to a continuance of a warm period, controlled by the excentricity, for nearly 500,000 years, when a great ice-age will again begin to affect the earth, unless tectonic changes intervene, such as have no doubt acted in the past. The Permian ice-age (p. 137) may be referred to the greater coolness of the large sea-area lying to the north of Gondwana Land, at an epoch of high excentricity, high obliquity of the ecliptic, with perihelion, as now, in the winter of the northern hemisphere.

In view of recent progress in physics, many geologists will prefer the hypothesis of variations in solar radiation as a possible explanation of great climatic changes; but this will not lessen their interest in Prof. Spitaler's detailed calculations.

G. A. J. C.

Our Bookshelf.

Capita Zoologica. Verhandelingen op Systematisch-Zoologisch Gebied. Onder Redactie van Prof. Dr. E. D. Van Oort. Deel I, Aflevering 1, *Nouvelles Recherches sur les Nématodes libres terricoles de la Hollande.* Par Dr. J. G. De Man. Pp. 62+14 plates. 10 guilders. Deel I, Aflevering 2, *Studien über Rhizostomeen mit Besonderer Berücksichtigung der Fauna des Malaiischen Archipels nebst einer Revision des Systems.* Von Dr. Gustav Stiasny. Pp. viii+176+5 plates. ('s Gravenhage: Martinus Nijhoff, 1921.) 16 guilders.

In these days of drastic economy it is becoming ever more difficult to find means for the publication of scientific work, especially when it has little or no direct bearing upon utilitarian problems. The systematic zoologist in particular has to content himself as a rule with as little as possible in the way of paper, letterpress, and illustrations, and it will probably be a long time before we see again in this country a series of zoological monographs comparable with that which embodies the results of the *Challenger* Expedition. Other countries, however, appear to be somewhat less embarrassed as to ways and means, and we are glad to welcome the appearance of a new Dutch periodical entitled *Capita Zoologica*, under the editorship of Prof. Dr. E. D. van Oort, Director of the State Museum of Natural History at Leiden. This publication will consist of a series of large quarto memoirs on systematic zoology, which will be issued separately as complete works as occasion requires. The first two are already published, dealing respectively with the free-living Terricolous Nematodes of Holland, by Dr. J. G. De Man, and with the Rhizostomatous Medusæ, by Dr. Gustav Stiasny. Both memoirs are fairly copiously, though by no means extravagantly, illustrated, and they form solid and valuable contributions to our knowledge of the groups with which they deal.

A. D.

Benzol: Its Recovery, Rectification, and Uses. By S. E. Whitehead. With an Introductory Note by the Rt. Hon. Lord Moulton. (The *Gas World* Series.) Pp. xiv+209. (London: Benn Brothers, Ltd., 1920.) Price 12*s.* 6*d.* net.

During the war the gas industry received a great impetus from the increasing demand for benzol and toluol for military requirements, and methods of recovery and production were adopted on a scale which was little appreciated at the time. One result of this was to pave the way for the foundation of a far greater benzol industry in this country than was previously existent, and the present volume has been written as a guide to the principles and practices engendered.

The text is most thorough, and while essentially practical, it does not ignore theoretical criteria cognate to the technicalities of the subject. The book is built up of exhaustive discussions of the recovery of benzol from gas, its rectification, and the uses to which it and the derivative products may be put. Probably the most interesting sections are those dealing with dyes, explosives, and the use of benzol as a motor fuel, which, although in the former connections modestly regarded by the author as summaries, are none the less useful and comprehensive. It is obviously important that, in view of this country's dependence on foreign resources of petroleum as a motor fuel, every effort should be made to ease the position by the establishment of a vast benzol industry, and in this effort the utmost encouragement should be given to those engaged in coal-gas production; the present volume is a valuable contribution to this end, and both for educational and technical purposes merits a wide circulation. H. B. Milner.

The Analysis of Mind. By Bertrand Russell. (Library of Philosophy.) Pp. 310. (London: George Allen and Unwin, Ltd.; New York: The Macmillan Company, 1921.) 16*s.* net.

The title of Mr. Russell's book may raise expectations that it is an exposition or development of his philosophical theory. It cannot, however, take rank with his great works. It is a course of lectures, to all appearance a verbatim report, which has been subjected to the very minimum of revision. It is brimming over with casual witty remarks which pass well with an audience, but will not bear reflection. The lectures show Mr. Russell under the influence of two comparatively recent popular movements in philosophy and psychology, both of which seem to have attracted him powerfully, and neither to have convinced him completely, namely, William James's Neutral Monism and Prof. J. B. Watson's Behaviourism. One lecture deals at some length with the question, "Does Consciousness exist?" The answer reminds one of the famous pronouncement that Shakespeare's plays were not written by Shakespeare but by some one else of the same name. It is easy enough to argue that consciousness does not exist, but then there is something we are talking about when we affirm its non-existence, and it is difficult to find any other name for it. In regard to Behaviourism Mr. Russell thinks it a beautiful theory and an ideal method, but then—there are images, and the theory cannot account for them.

(1) *Aspects of Plant Life, with Special Reference to the British Flora.* By R. L. Praeger. (Nature Lover's Series.) Pp. 208. (London: S.P.C.K.; New York: The Macmillan Company, 1921.) 6*s.* net.
(2) *Mountain and Moorland.* By Prof. J. A. Thomson. (Nature Lover's Series.) Pp. 176. (London: S.P.C.K., 1921.) 6*s.* net.

There are many educated persons who are conscious that they miss much of the beauty and interest of the world around them through lack of knowledge and of the seeing eye that knowledge alone can give. To all such these two small volumes published by the S.P.C.K. will prove most acceptable. In an easy and non-technical fashion (1) Prof. Praeger sets forth the conditions under which various types of flowering plants exist, the problems by which they are confronted, and the devices by which they triumph. He brings forcibly to mind the deep philosophical nature of the questions that may be raised by the occurrence on hill or in valley of even the humblest plant.

(2) Prof. Arthur Thomson's book is a delightful companion for any one who wishes to enjoy intelligently a holiday among our moors and mountains. It touches in a stimulating and suggestive way on almost every branch of natural history in these favourite districts, and opens out numerous fields of research for the reader.

Practical School Gardening. By P. Elford and S. Heaton. Second Edition. Pp. 224. (Oxford: At the Clarendon Press, 1921.) 3*s*. 6*d*. net.

Messrs. Elford and Heaton have had very considerable experience in organising school gardens and making them fit into the educational scheme, and they have produced a volume which has already proved its usefulness, so that it now passes into a second edition. The authors insist that the combination of School Gardening and Nature Study when properly co-ordinated with the rest of the work in the school can be, and often are, a valuable means of education. Most teachers would agree, but difficulties do undoubtedly arise when an attempt is made to put this excellent general principle into practice. Given a plot of ground, a class, and a limited but definite time each week, how is the teacher to proceed in order that the children may derive the maximum educational benefit? The practical details that need attention, the pests, weeds, and other troubles that are likely to cause trouble, and the many difficulties that crop up as soon as one begins to cultivate the soil, are effectively dealt with. The authors urge that a school reference library might with advantage be formed, but they give no suggestions to this end. In a future edition a list of suitable books might well be added.

Laboratory Manual of the Technic of Basal Metabolic Rate Determinations. By Dr. W. M. Boothby and Dr. Irene Sandiford. Pp. 117. (Philadelphia and London: W. B. Saunders Company, 1920.) Price 24*s*. net.

The authors consider that the results of indirect calorimetry should not be thrown into general discredit as a means of clinical diagnosis, by neglect of details requisite for a true basal metabolic rate. In their well-illustrated book they have certainly set a good example in the matter of detail. They describe the method in use at the Mayo Clinic, Rochester, Minnesota. The patient inspires the atmospheric air through a mask, and the expired air is collected and measured in a gasometer (Tissot) from which samples of air are taken for analysis of carbon dioxide and oxygen by the Haldane gas analysis apparatus, the calculations being carried out as usual. The advantages of this method, and perhaps the disadvantages of other methods, are somewhat emphasised. The authors deserve credit for the very careful directions for all stages of the technique. The book contains a special note for calculation of metabolic rate of a diabetic, a bibliography, an appendix with all the tables required for calculations, and an index. Indirect calorimetry has certainly proved its value in cases of thyroid disease.

Some Account of the Oxford University Press, 1468–1921. Pp. 112. (Oxford: Clarendon Press, 1922.) 5*s*.

This is a charming monograph describing the work of a great institution. The book is a masterpiece of typography, and is embellished by a number of reproductions of old woodcuts and recent photographs. Special chapters are devoted to its most important publications—the Oxford English Dictionary and the Dictionary of National Biography. The vast operations of the Press may be judged by the fact that its warehouses at Oxford are estimated to contain 3½ million copies of about 4500 distinct works. From these vaults was drawn into the upper air, in 1907, the last copy of Wilkins's "Coptic New Testament," published in 1716, the paper scarcely discoloured and the impression still black and brilliant. During the War, the Press carried out much confidential work for the Naval Intelligence Department, and supplied during three years 4½ million copies of the New Testament for use in the field. The relations of the Press to its servants have always been amicable, and the case of the late Mr. J. C. Pembrey, one of the proof-readers, is probably unique: in 1847 he read Wilson's "Sanskrit Grammar," and in 1916 the "Vedic Grammar" of Prof. Macdonell.

Animal Life of the British Isles: A Pocket Guide to the Mammals, Reptiles, and Batrachians of Wayside and Woodland. By E. Step. (The Wayside and Woodland Series.) Pp. vii + 184 + 111 plates. (London and New York: Frederick Warne and Co., Ltd., 1921.) 10*s*. 6*d*. net.

This handy little volume will be welcomed by a large number of amateur naturalists, and can be cordially recommended to all who wish for full and accurate knowledge of the habits, life histories, and appearances of those members of the British fauna that are included in the three classes specified in the sub-title. Hitherto it has not been possible to secure such information within the covers of a single small volume, nor in any one work at so low a price. The illustrations are excellent, the plain being from the work of our best naturalist photographers, such as Messrs. Douglas English, Oxley Grabham, and others, while forty-eight photographs in the natural colours are to the credit of Mr. W. J. Stokoe. The co-operation of these talented artists with the author results in a very satisfactory pocket guide.

British Insect Life: A Popular Introduction to Entomology. By E. Step. Pp. 264 + 32 plates. (London: T. Werner Laurie, Ltd., N.D.) 10*s*. 6*d*. net.

Attempts to give "popular" accounts of the several orders, families, and other subdivisions into which insects are classified almost invariably fail from lack of the courage needed to set before the general reader those details of structure that must be mastered in order to discriminate order from order, genus from genus, and, still more, species from species. In the absence of such information books such as this by Mr. Step become, except to those already versed in entomology, meaningless in many of their pages. We should welcome statements which would enable the enthusiastic beginner to determine whether the specimen in his hand was, say, a stone-fly, a may-fly, a lacewing-fly, or a caddis-fly; and others rendering clear the structural differences between, say, the pierid and the nymphalid butterflies; and so on. We decline to believe that shirking the difficulties will ever popularise or in any way benefit the science of entomology. The figures in the plates of this book are unfortunately not numbered; thus the uninstructed reader is left in doubts as to the application of the numbers given in the respective legends.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mind.

THERE seems to me now to be some prospect of agreement that, since all characters are equally products of nature (potentiality, capacity, predisposition, diathesis) and fitting nurture, all must be equally innate, acquired, germinal, somatic, and inheritable. *If* that be the case, the problem of inheritance is settled. Doubtless some biologists will continue to discuss such things as the transmission of characters and the intensity of inheritance, but the impossibility of defining their terms and explaining what they mean will always vitiate their labours.

Whatever other tasks biology has before it, two are of prime importance: (*a*) to determine what characters are evoked in individuals by such influences as food, moisture, light, temperature, hormones, use, injury, and the like, and (*b*) to trace the evolution of races, which implies tracing the changes in their natures (*i.e.* in germ-plasms as indicated by changes in characters), which, since the nature of every race is the sum of its potentialities, in turn implies tracing changes in potentialities for development. In both these tasks biology must seek its data from the subsidiary sciences of physiology and psychology.

The kinds of nurture with which we are most familiar, and which we can most easily observe in action, are injury and use. Here, therefore, we are best able to note to what extent individuals are capable of developing in response to given influences, and to what extent species have altered with respect to their capacities for development. Both injury and use confer adaptability on the individual. Injury need not detain us long. Many plants and some lower animals are capable of developing greatly in response to it. Thus a begonia or a sponge may be completely regenerated from a fragment. A lobster can regenerate its claw and a lizard its tail. Higher animals merely heal injuries by means of scars. In them this capacity has undergone retrogression and has been replaced (or supplemented) by that which confers much more adaptability—the capacity of developing in response to use.

It would seem that the power of developing in response to use is a late and a high product of evolution. At any rate, since it is inappreciable in low, and progressively more evolved in higher, animals, presumably it must have had a beginning somewhere in the scale. Presumably also, since a structure cannot be used before it exists, the individual recapitulates in this particular, as in others, the evolution of his race.

The evidence is much clearer as regards mind. I take it that mind is associated with movement; its function is to cause the individual to take action. A reflex action may be associated with consciousness. Some reflex actions (*e.g.* sneezing) are even initiated by consciousness. Some (*e.g.* breathing) can be controlled to some extent by the will; but no reflex action is *initiated* by the will. Thus, when we cough at will the action is not reflex. Reflex actions, therefore, may be defined as those which are initiated by stimuli other than will. On the other hand, an instinct is always and altogether a mental thing—a mental impulse, an emotion, an inclination, a desire to do a certain action, the instinctive action. Like reflexes, it develops in the individual apart from mental experience which merely awakens it to activity, but does not create it. In other words, an instinct is not learned; it is not a product of the functional activity of the mind, but develops in response to quite different influences (*e.g.* hormones). It is not a complex reflex; some reflex actions (*e.g.* sneezing) are quite as complex as some instinctive actions (*e.g.* infantile crying). An instinctive action differs from a reflex action in that it is always *voluntary*. The individual performs the action because he *wants* to do so. If there were no desire, there would be no action. I am aware that all this is unorthodox. Nevertheless, it is true, as any one may discover by examining his own instincts. Does he not, for example, eat, and drink, and sport, and make love through desire? Did he *learn* to feel these desires? I am aware also that at this stage it is customary to discuss the metaphysics of mind and will. I have tried to do so elsewhere, but it is unnecessary here. It is enough that mind, including will, exists and appears to influence the body as gravitation appears (as incomprehensibly) to influence the planets. Instinct may be defined as desire which develops in response to influences other than functional activity.

Habit, intelligence, and reason are in a different category. They are all products of learning, of mental growth due to the functional activity of the mind. An animal is intelligent in proportion as it profits mentally from experience—that is, in proportion as its past sheds a light on, and serves as a guide for, its present and its future. The animal then stores experiences and *re*collects them. Thus its mind grows. We have given a special name to the power of growing mentally in response to use, though the word is used somewhat vaguely. We call it memory. We speak of a man with a good or bad memory, with good or poor powers of learning.

There are two sorts of memory, conscious and subconscious. Again I am unorthodox, but my words have real meanings. We learn two sorts of things: (*a*) facts and the like, which we can recall to mind and which belong to the conscious memory, and (*b*) skill and facility in thinking and doing (mental habits) which cannot in the same sense be recalled, and which, therefore, belong to the subconscious memory. For example, I can recollect a good deal about golf clubs, balls, courses, and adventures; but all this is quite distinct from other sorts of learning, which I cannot in the same sense recall, and, therefore, cannot describe, which enable me to play skilfully (to a humiliatingly small degree). The greatest golfers do not know the very names of the muscles which they have learned to co-ordinate with such exactness and facility.

Consider the caterpillar. He comes out of the egg and, equipped with instincts, at once sets about the business of life. He seeks his food and devours it; he hides from enemies; at the proper time and place he builds a cocoon, and as a butterfly does all sorts of new actions of which also he can have had no previous experience. Apparently he learns nothing; he has little or no memory. Learning would be useless to him; for, unprotected and untaught as he is, he must always act correctly and at once, or perish. He can "bear in mind" for a little while, as a sound lingers on a harp-string. But he cannot recall, as a sound is reproduced by a gramophone. He can feel (*e.g.* pleasure and pain, desire and aversion), but he cannot think (compare, associate, imagine, and the like); for without learning he has nothing to think about. Because his past is a blank he cannot forecast his future, which, therefore, is a blank also. He lives only in the immediate present—a knife-edge of time. Since he has little or no power of profiting by

experience, he is not adaptable; he moves in much the same groove as did his ancestors of a million years ago.

Higher than the caterpillar in the animal scale, the power of growing mentally in response to functional activity is clearly in being. Animals are able to recognise mates and offspring, and the latter are able to recognise their guardians. Family life begins. The offspring, more or less helpless at birth, but protected by their guardians, have ability and opportunity to develop physically and mentally in response to functional activity until they are able to fend for themselves. They begin to think, they become adaptable. This evolution culminates in man, who is born so helpless that he cannot even seek the breast, but who learns so enormously that he becomes rational. Reason is merely intelligence *in excelsis*. A vast and complex store of experience then lights a complex, and perhaps distant, future. Compare three human individuals—an idiot, a newly born baby, and a normal man. The idiot cannot learn, and has not learned; the baby can learn, but has not learned; the normal man can learn, and has learned. There in a nutshell is all the mental difference between them, except that the baby has not yet developed a few instincts. The idiot has these instincts, but, probably because he has lacked some hormone, has reverted by mutation (himself or by some progenitor) to an enormously remote ancestry in which the power of learning was defective. One day I think we shall cure idiocy by the injection of the proper glandular extract. Compare a man with a dog: how enormously greater is the human power of learning, and, therefore, of thinking. Compare him with a housefly: the fly settles on the hand; we strike at it; impelled by instinct, it shoots away; a moment after, having ceased to "bear in mind," it is back again, unmindful of a danger the recollection of which would set a man shuddering for years. We are able to domesticate animals only when they have the capacity to learn to tolerate, to obey, and, when the intelligence is very great (*e.g.* dog), even to love us. Savage man is so intelligent that he has invented language by means of which he is able to hand on the accumulated traditions of generations. Civilised man differs from him in that he has invented aids to his powers of remembering (*e.g.* books of reference), of thinking (*e.g.* mathematics), and of doing (*e.g.* tools). The retrogression of instinct and its replacement by intelligence is well illustrated by maternal care among brutes and men. Among the former it is instinctive, but women have to learn how to tend their young. Again, while insects walk instinctively, men learn. Among the higher animals the number of offspring is controlled by the number which can be protected and taught.

This or that naturalist may disagree as to this or that detail of what I have written about mind, but with the main argument I think all must agree. Already, in practice if not in theory, actions which are not initiated by the will are called reflex; those which are initiated by the will, but in which learning plays no part, are called instinctive; while those which are both initiated by the will and result from learning are called intelligent. As to the evolution of the potentiality of developing in response to use, the truth is glaringly obvious. Even a schoolboy knows that he can teach a beetle nothing, a cat a little, a dog more, and a child much. But all this is incompatible with Lamarck's first law, which has met with such general acceptance. As regards body, the evolution may be more difficult to trace. At any rate, it has not been studied. But as regards mind it is as clear as sunlight. Plainly, an animal is intelligent in proportion as it is able to profit from experience; man's reason and intellect depend wholly on his power of learning; and, as well as I can judge, whenever an animal is capable of learning it is also capable of developing physically in a corresponding degree in response to the stimulus of use.

G. ARCHDALL REID.

9 Victoria Road South, Southsea, Hants.

Pencil Markings in the Bodleian Library.

IN a former communication (NATURE, 1920, vol. 105, p. 12) I described a method of distinguishing microscopically between the markings made upon paper with different kinds of pencils, and gave some account of the characteristics of early pencil writings in the British Museum.

I am now indebted to the Librarian of the Bodleian Library and to Dr. Craster for their kindness in giving me facilities for studying similar early specimens of pencil writing in that library.

In Schönemann's work on the examination of early MSS. ("Versuch eines Systems der Diplomatik," 1818, vol. ii. p. 108) it is stated that the ruled lines in various documents of the eleventh and twelfth centuries are in a graphite pigment. Referring to this statement I pointed out (*loc. cit.*) that, since graphite was only discovered in 1560, it was obvious that Schönemann must have mistaken ordinary metallic lead for graphite.

The historical basis for my criticism is to be found in Gesner's "De Rerum Fossilium Lapidum et Gemmarum Genere," 1565, vol. ii. p. 105, and in Beckmann's "Beiträge zur Geschichte der Erfindungen" (1780). It appears, however, that graphite must have been known long before that time, for, after reading my communication, Prof. Flinders Petrie informed me that he had discovered a lump of graphite at Ghorub, which must have dated back to a period between 1500 and 1200 B.C., although there was no evidence that graphite was ever used as a pigment in ancient Egypt.

This unique specimen of graphite, a portion of which Prof. Flinders Petrie has kindly given me for examination, is a decidedly coarse, impure mineral, containing only 39·4 per cent. of carbon, and the amount of silicious impurities present is plainly indicated by the pronounced irregular striations in the markings on paper.

This proof that graphite was known ages before its reputed discovery in 1560 in the Borrowdale mine, gives an added interest to the examination of the earliest pencil markings available in this country.

The earliest known instance of pencil marking in the Bodleian is a vellum MS. Commentary on the Book of Job of the thirteenth century (Auct. D. iii. 14). This has vertical lines, ruled with a stylus down the sides of the writing, and the microscope shows that the pigment of these is lead or other metal.

In the "Opuscula Varia SS. Augustini et Bernardi" of the thirteenth and fourteenth centuries (Hatton MS. 102), the ruled lines surrounding the text are in a red ink in some of the MSS., whilst in others they are in a metallic pigment. In another Hatton MS. (No. 107) of the fourteenth century, no pencil markings are present, the ruled lines at the side and the annotations being in a pale brown ink.

The "Opera Johannis Dastyn" of 1590 (Bodl. MS. 485) is written in ink, and shows pencil strokes at the side written in graphite, but there is no evidence that these markings were contemporaneous with the body of the MS.

An Italian MS. on paper, "Geomantia" (Digby MS. 133), written in ink prior to 1634, shows fine ruled lines at the side in a brilliant metallic pigment;

and the annotations in a Hebrew MS. "Jad Chazaka" (Poc. 235) of about 1650 are also in lead or a lead alloy.

The notebook of the Swiss scholar Casaubon, (Casaubon MS. 61), written about 1613, is particularly interesting. The leaves of the book are of thick horn and are covered on each side with minute writing, which is in a metallic pigment, showing much finer spicules than is usual in the writing done with a metal style. It resembles the pigment used in the drawings of the Stowe MS. "Arms of Ancient Nobilitie" of the early seventeenth century (British Museum).

A series of almanacs interleaved and containing Anthony Wood's Diary from 1676 to 1685 (Wood's Diaries 20–29, 742), shows ruled lines in a metallic pigment, while the entries in the diaries are either in ink or, less frequently, in pencil. Referring to the latter entries, the Rev. Andrew Clark remarked ("Life and Times of Anthony Wood," I. 3 Oxf. Hist. Soc., 1891): "Wood's pencil, I assume, was not graphite, but actual lead. It has left a faint mark, almost illegible, except for the indentation of the paper." Microscopical examination of these entries down to 1685 showed that this assumption was correct, none of the writing having the characteristics of graphite.

At a later date, however, Wood appears to have had a graphite pencil. "A Collection of Poems on Affairs of State," London, 1689 (Wood, 382) has a note on its flyleaf in the writing of Wood: "Bought at Oxon. 26 Feb. 1688." (The discrepancy between the dates is explained by the use of the old style for one of them.) This writing has the appearance of ordinary graphite, the masses of black pigment being uniformly distributed, and none of the particles showing the lustre or striation of lead or its alloys.

With the very doubtful exception of the markings in the MS. of Johannis Dastyn (*supra*), this is the earliest writing in graphite pencil noted in the Bodleian Library.

It will be recalled that the earliest graphite writing found in the British Museum was in two Notebooks of Sir Thomas Cotton, one of about 1630–1640 and the other 1640–1644.

C. AINSWORTH MITCHELL.
195 Victoria Street, S.W.1.

Haloes and Earth-History: A New Radioactive Element.

IN the Archæan black mica of Yitterby, very small, colourless, spherical, halo-like forms occur. The mica is, as it were, bleached within these halo-spheres. Many show a central opaque particle or nucleus. In the case of others it is difficult to be sure of the presence of a nucleus, or it may take the form of a limpid refracting particle. The optical appearances suggest that in these spheres the refractive index of the mica has been raised.

They are very small. A cluster of these minute haloes, amounting to many hundreds, presents with a low power the appearance of a starry sky. The average diameter appears to be 0·01 mm., no allowance being made for the nucleus. The greater number are remarkably uniform in diameter. Thus, readings of 23 of these haloes, taken at random, range from 50 to 59 scale divisions of the micrometer. A few larger ones are present, but, as in most cases their greater size is directly referable to an aggregation of nuclear particles occupying a large central volume, it seems safe to conclude that these limpid spheres are in reality of one size only.

The mica flake in which this cluster occurs is 0·018 mm. thick, or perhaps a little less. The minute spheres are located at various depths in the mica—some below the surface, some more or less truncated. Many are sharp and easily measured; others, as would be expected, are diffuse upon the edge.

I have been for some years aware of the existence of these haloes—since a period before the war—but, during the occupation of my laboratory by troops in 1916, among other things lost was the specimen of Yitterby mica from which my slides were obtained. A few other samples of this mica did not appear to contain them. Nor could I form any probable theory to account for them. Their uniform size convinced me that they were radioactive. The hypothesis that they might be due to slow β-radiation had really nothing to support it: no similar effect having been found in any other mica. Later I concluded that they must be reversed haloes such as I found in the Devonian mica of Co. Carlow. There were other appearances to support this view. Thus in the very similar Archæan mica from Arendal, bleached uranium haloes in various stages were found. Again, in both the Yitterby and Arendal mica, semi-bleached bands occur having a centrally placed line of what are probably radioactive particles disposed like a central moraine on a glacier. But with these appearances of reversal were vigorous haloes in all stages of development.

Recently, Dr. Prior was so good as to send me some flakes of Yitterby mica. In them I found all the appearances described above, including a few of the minute bleached halo-spheres.

The idea that this bleaching of the Archæan micas might be due to former high temperature conditions led to a test of the behaviour of the Carlow mica at different temperatures. It was found that a halo-rich specimen of this mica after an hour's exposure to a temperature of about 730° C. had acquired many of the characters of the Archæan micas. Most of the haloes had disappeared, and some had left a bleached area giving quite characteristic readings. Bleached bands, also, had taken the place of linear radioactive staining; and the originating radioactive particles were exposed to view forming a central line.

There is, I think, no doubt that these (and other) appearances show that the Yitterby and Arendal Archæan micas were at some remote period subjected to a temperature probably not much exceeding 700° C. during which a prior-existing crop of haloes were obliterated or reversed, and that, therefore, the existing haloes are a second crop which originated from the same nuclei when the thermal conditions permitted their development. This history has a good deal that is fortuitous connected with it. Some three hundred additional degrees of temperature would have reduced the mica to a slag.

But what is to be inferred as to the nature of the minute halo-spheres? A chance find seems to bear upon their origin.

In the mica of Arendal uranium haloes are fairly abundant; they occur in every stage of development. Within some of the earliest rings having radial dimensions reading from 0·0150 to 0·0160 (corresponding to rings which in Devonian mica read 0·0145) a very minute ring is sometimes seen. It is a difficult object and needs good lighting and good sight to detect. This ring surrounds the point-like nucleus with perfect centricity, an intervening band of unstained mica being apparent. The radius of this ring has been read from 0·0049 to 0·0057. The effect of the nuclear dimensions on a ring so small

is considerable. I make no correction for it here. Presumably we are dealing with an α-ray of the same range as that which must have been concerned in the genesis of the Yitterby haloes.

This range, if taken as 0·005 mm., would correspond to about 1 cm. in air at 15° C. The radioactive element concerned, although associated with the uranium family of elements in the Arendal mica, cannot be a member of that family. This appears from the value which in such a case we must ascribe to λ. It would decay at a rate some billions of times slower than uranium according to an extrapolation on the Geiger-Nutall curve. Now the ring in the Arendal mica must have been formed since early Archæan time and from a nucleus of point-like dimensions.

From all this there seems good evidence that a radioactive element exists (or formerly existed) emitting an α-ray having a range of about one centimetre in air. So far no evidence of its further disintegration has been found.

It seems probable that the development of the small Yitterby halo-spheres represents a very considerable period of time. It will be of interest to see if similar evidence for what appears to be a very long period of Earth-history, seemingly preceding early Archæan time, will be forthcoming from material found elsewhere. It is possible that this period preceded the thermal conditions which generally prevailed during Archæan time and that the survival of the evidence contained in the Yitterby mica was due to local fortuitous conditions. These haloes would, in that case, be a record carried from one geological age to the next.

I wonder am I justified in naming an element from such evidence as I have found—the range of an α-ray? I think it has been done before. If ever it is isolated I would ask the finder to call it Hibernium after this beautiful but most unhappy country.

J. JOLY.

Trinity College, Dublin, April 8.

The Helmholtz Theory of Hearing.

ON a visit to the Cambridge Physiological Laboratory not long ago Dr. Hartridge demonstrated an apparatus of his design that showed the effect of a repeated sinusoid vibration on a series of pendulums of different periods. Each of a series of weights was suspended from a horizontal bar. The strings were all of different lengths; each pendulum had thus a different period. The horizontal bar was connected with a wheel so that it could be moved back and forth harmonically.

When the wheel was started, all the pendulums began to vibrate. As the wheel continued its rotations, the pendulums gradually came to rest—except one, namely, that one the natural period of which corresponded with that of the rotating wheel. This proved that with a continuous series of vibrations only a pendulum with a harmonic period would be maintained in vibration. It also proved that a single vibration set *all* pendulums in vibration no matter what natural periods they might have. Dr. Hartridge has thus demonstrated that if the ear possesses a series of resonating organs *every one* will respond to the first vibration and will come to rest only when this vibration has been several times repeated.

When a person sings a glide from one note to another, his voice produces vibrations that are all different. Every one of these vibrations is the first of its kind, and at no moment is there a succession of waves of the same period. Consequently at every single vibration *all* the resonators in the ear are set in vibration, and this vibration of all of them continues throughout the glide. In speech the voice is never still for an instant. Every vibration from the larynx differs from the one before. Therefore in perceiving speech *every* resonance organ of the ear must act at every instant for every vibration of the voice.

Dr. Hartridge has given a complete and final proof that, if the ear possesses a set of resonating organs, they must all respond together for each new vibration; as the changing tone of speech has a new vibration at every instant, they must all respond alike at every instant and for every tone.

According to the Helmholtz theory each vibration acts on a different resonator in the ear. In the sliding tone always used in speech each single vibration must, according to Helmholtz, pick out a corresponding resonator. It is easy mathematically to show that this cannot be true and that each single vibration of the voice in speech must set all resonators in action. Nobody seems to have thought of this, and it has remained for Dr. Hartridge's highly ingenious apparatus to kill finally the Helmholtz theory of hearing.

In the April number of the *British Journal of Psychology*, Dr. Hartridge gives as the fundamental reason for supporting the Helmholtz hypothesis that the experiments described by him show that there are resonators somewhere. As pointed out above, they show exactly the opposite, namely, that there cannot be any resonators anywhere. If there cannot be any resonators, then the hypothesis that the ear acts as a resonating apparatus becomes an impossible one.

E. W. SCRIPTURE.

Boyle's Experiments on Capillarity.

IN Mr. Hardy's interesting "Historical Notes upon Surface Energy and Forces of Short Range," NATURE, March 23, p. 375, he says that "Boyle tried, but failed, to observe whether the (capillary) rise took place in a vacuum." Boyle writes in Experiment XXXV. of the "New Experiments Physico-Mechanical" that after showing the capillary rise in open air, "We tried indeed, by conveying a very slender pipe and a small vessel of water into our engine (air pump receiver), whether or no the exsuction of the ambient air would assist us to find the cause of the ascension we have been speaking of; but though we employed red wine instead of water, yet we could scarcely perceive through so much glass, as was interposed betwixt our eyes and the liquor, what happened in a pipe so slender, that the redness of the wine was scarcely sensible in it. But, as far as we could discern, there happened no great alteration to the liquor; which seemed the less strange, because the spring of that air, that might depress the water in the pipe, was equally debilitated with that, which remained to press upon the surface of the water in the glass." Boyle was a very careful and accurate experimenter, and he was trying to find whether there was an alteration in the capillary height *in vacuo*. His experiment was quite accurate and is worthy of his great reputation.

SIDNEY SKINNER.

Problems in the Variability of Spectra.[1]

By Prof. THOMAS R. MERTON, F.R.S.

IT has been known for many years that the radiations which an element emits in the state of a luminous gas are not invariable but depend on the presence of other elements, the manner in which the substance is excited to luminosity, and other circumstances. It was recognised in some of the earliest investigations that many band spectra were to be associated with compounds and that a spectrum might be due partly to such compounds and partly to uncombined atoms. Thus, for example, if strontium chloride is introduced into the flame of the bunsen burner we find lines associated with the element, bands due to strontium oxide, and also bands due to the chloride, and when strontium bromide is substituted for the chloride the spectrum is the same as regards the lines due to the element and the oxide bands, but bands peculiar to the bromide are found to have replaced those due to the chloride.

Minute quantities of substances can sometimes be detected by means of these characteristic bands due to compounds, a familiar example being the blue flame which is seen when common salt is thrown onto a coal fire and is due to the copper chloride formed from the chlorine in the common salt, and the minute trace of copper which is present in the coal. A number of different elements are present in most flames, and the reactions which occur are probably very complex. In gases contained in vacuum tubes which are excited to luminosity by electrical discharges it is possible to work with pure substances, and a discussion of the spectra observed is simpler.

In the case of gases in vacuum tubes the spectrum sometimes consists of bands, and the band spectrum from the negative pole may be different from that seen in the positive column. Thus nitrogen, when excited by uncondensed discharges, shows in the visible regions two band spectra, one known as the positive band spectrum, which appears in the capillary of a vacuum tube of the conventional type, and the negative band spectrum, found in the neighbourhood of the cathode, which constitutes an important part of the spectrum of the aurora.

Both these band spectra, and indeed all band spectra, are generally attributed to molecules rather than atoms, but if a condensed discharge is passed through nitrogen the spark spectrum associated with the nitrogen atom is obtained, and this is capable of further modification when discharges of great intensity are employed. The action of the condensed discharge is almost certainly due to the greatly increased current density which obtains during the very brief periods while the discharge is passing. Its first effect is to break up the molecules into atoms, and the further stages brought about by an increase in the intensity of the discharge are generally supposed to be due to the removal of successive electrons from the atoms. There are other methods by which the current density can be increased with similar changes in the spectrum; the effect of an increase in the current density is to increase the number of charged particles in a given volume of the gas, with the result that a large number of the radiating atoms are subjected to intense electric fields due to neighbouring charged particles.

Similar results are observed in the spectra associated with carbon. There are at least six spectra due to compounds of carbon with hydrogen, oxygen and nitrogen, and special experimental conditions are necessary for the production of some of these spectra. In addition to these band spectra carbon shows line spectra, and with the most intense discharges which can be employed in the laboratory a number of new lines appear which are also found in the spectra of the hottest type of stars, known as the Class O, or Wolf-Rayet stars.

All these changes can be reasonably accounted for, but there are a number of other changes which are more difficult to explain. For many reasons the spectrum of hydrogen is of particular interest, because the atom of hydrogen is the simplest known atom and is supposed to consist of a positive nucleus and a single electron. There are two spectra associated with hydrogen, one of which, the Balmer series, is found in almost all celestial spectra and also in vacuum tubes in the laboratory unless the most rigorous precautions are taken to exclude all traces of hydrogen. The explanation of the origin of this spectrum has been one of the most striking successes of the quantum theory of spectra developed by Bohr and by Sommerfeld. The other spectrum of hydrogen, known as the secondary spectrum, consists of an enormous number of lines and differs in its mode of production from the Balmer series in that the secondary spectrum is characteristic of pure hydrogen. In the purest hydrogen obtainable the secondary spectrum may be as bright as the Balmer series, but if the smallest trace of impurity is present the Balmer series gains in intensity and the secondary spectrum becomes very much weaker. In a vacuum tube containing water vapour the lines of the Balmer series are extremely intense whilst those of the secondary spectrum are relatively very faint. The investigations of Michelson and Lord Rayleigh, and of Buisson and Fabry have shown that under certain conditions the masses of the atoms or molecules from which the spectrum originates may be deduced from a knowledge of the widths of the spectrum lines, and recent investigations, in which the widths of the lines of the secondary spectrum of hydrogen have been measured to a high degree of precision, have shown that the secondary spectrum is to be referred to the hydrogen molecule.

The presence of impurities in vacuum tubes containing hydrogen not only enhances the lines of the Balmer series but also brings about changes in the relative intensities of the Balmer lines themselves. Some of these changes are very striking, but there are other variations of a more subtle kind which are only discovered when accurate quantitative measurements are made of the relative intensities of the lines. A most striking effect is observed when a relatively large quantity of helium is admitted to a vacuum tube containing hydrogen. Under these conditions the

[1] From a discourse delivered at the Royal Institution on Friday, March 10.

relative intensities of some of the lines of the secondary spectrum alter in a surprising manner, some of the lines being greatly enhanced whilst others become very weak.

From a theoretical point of view the spectrum of helium is second in importance only to that of hydrogen. The lines of helium are prominent in the spectrum of the chromosphere of the sun and of many stars, and their relative intensity varies under different conditions of excitation in the laboratory and in different celestial spectra. There are six chief series of lines in the spectrum of helium, three of which are usually referred to as the "helium" and three as the "parhelium" series. The helium series are the stronger in vacuum tubes containing the gas at pressures exceeding a few millimetres, whilst at very low pressures the parhelium series are predominant. Since the chief visible line of the helium series is yellow and that of the parhelium series green, the colour of the discharge is changed from yellow to green when the pressure is reduced.

There is another spectrum associated with helium which is analogous to the secondary spectrum of hydrogen in that it appears with any considerable intensity only when the gas is exceedingly pure. This spectrum is known as the band spectrum of helium, and its occurrence in a gas which is known to be incapable of forming molecules in the chemical sense of the word is very remarkable, in view of the fact that band spectra are generally attributed to molecules. It may perhaps be suspected that there is some temporary association of atoms during the passage of the electric discharge which cannot be referred to as a molecule in the chemical sense of the word. Prof. A. Fowler has shown that the arrangement of the heads of the bands in this spectrum resembles that found in series of lines which are due to atoms, though the arrangement of the lines which constitute each band is of the type usually found in band spectra.

When powerful condensed discharges are passed through helium a spark spectrum is developed. Two series in this spectrum are known as the 4686 and the T Puppis series, and their discovery by Prof. Fowler has led to some of the most important developments of theoretical spectroscopy. These spark lines of helium are found in the nebulæ and early type stars, and are attributed to helium atoms which have lost an electron.

The energy required to produce spark spectra varies widely with the nature of the gas under investigation, and for elements of the same chemical group is, as a rule, smaller the greater the atomic weight of the element. Thus in the case of helium powerful discharges are required for the production of the spark spectrum and the lines of the arc series are always bright. In the case of argon a much less intense discharge is required to produce the spark lines, and with very powerful discharges the arc lines disappear almost entirely from the spectrum. In addition to the production of these spark spectra one of the effects of powerful condensed discharges is to alter the relative intensities of the arc lines. Generally speaking, the effect of an increase of energy on a particular series of lines is to enhance relatively the more refrangible members of the series, but the effect varies in degree for different series. Experiments of this kind enable us to imitate to some extent in the laboratory the distribution of intensity amongst the lines which is found in the nebular and stellar spectra.

It will be seen that whilst many variations in spectra can be referred to different compounds, to molecules, and to uncombined atoms in successive stages of ionisation, there are a number of other changes for which there is at present no obvious theoretical explanation. The possibility of some specific influence of one gas on the spectrum of another must now be recognised apart from the formation of chemical compounds, which, in the action of helium on the spectrum of hydrogen, for example, appears to be excluded. There is also other evidence, based on a study of the broadening of spectrum lines, of a specific action on neighbouring atoms. We are still awaiting a satisfactory theoretical explanation of phenomena of this kind, though it is now forty years since what is perhaps the first known example, the action of sodium on the absorption spectrum of magnesium vapour, was observed by Prof. Liveing and Sir James Dewar at the Royal Institution.

Mathematics and Public Opinion.

PERHAPS few well-known mathematicians have escaped an experience which would be amusing if it were not so exasperating. Mr. Brown (let us say) is introduced to Prof. Smith, who teaches mathematics at a provincial college. After the usual expression of pleasure at the introduction, Brown generally adds "Of course, although I haven't had the pleasure of *meeting* you before, I know you well by reputation." Then, without so much as pausing to take breath, he proceeds to explain that he was always a duffer in "maths" at school, and that he has now forgotten everything about the subject they tried to teach him as a boy. Now Brown doesn't act in this way to every celebrity. If introduced to Dr. Lasker, and unaware that he is a distinguished mathematician, he does not seize the first opportunity of telling him that, although he occasionally plays draughts with his wife in the evening, chess was always beyond him, and he could not remember the simplest openings. Still less does he act in this way if his new acquaintance is a sportsman or an epicure. Moreover, in making his lamentable confession, Brown shows no sign of regret or humiliation; on the contrary, a sort of satisfied look steals over his face, suggesting that he is glad to be free once for all from the study of such a repulsive and useless subject. England is perhaps the only country where such an occurrence is fairly frequent; and this fact suggests some very unpleasant reflections.

One thing clear from Brown's attitude is that he evidently fears lest Smith should introduce some mathematical topic during the conversation. Of course this is the thing Smith is most unlikely to do. If this were all, it would be as harmless as the caricatures of professors and policemen which we see on the stage. But there is a very serious additional

reason for Brown's behaviour. An admirable Report has just been published in which it has been thought necessary to emphasise the obvious fact, that an English student who intends to pursue a course in the humanities must, first of all, have a sound and fairly extensive knowledge of his own language and literature. Unless this foundation is well and truly laid, the student's equipment is imperfect, and he is severely handicapped at every turn.

Now, mathematics occupies a precisely similar position with regard to a course in science. To give a full justification of this statement is, of course, impossible here; but an attempt to do so partially will be made by putting an imaginary case. Let us suppose that progress in mathematics had stopped abruptly at the end of the 15th century, a comparatively recent date in the history of the science. The result would be that physics would be almost entirely empirical; there would be no theories at all to account for the motions of the heavenly bodies, for the transformations and indestructibility of energy; no general theories, capable of verification, in physical optics, heat, or electricity. It is extremely unlikely, not to say impossible, that instruments like modern telescopes, microscopes, spectroscopes, or electric and electromagnetic meters of various kinds, could have been invented. Some, at least, of the consequences involved in this can be seen by everyone who considers the matter.

To turn to more banausic or, if the reader prefer it, practical considerations: a single example must suffice. Let us suppose that "practical" engineers had succeeded in constructing a steel steamship, approximating to the modern type. (This in itself is taking a good deal for granted.) The induced variations of its compass would have to be corrected by a blind and tedious process of trial; the skipper would have no Nautical Almanack, no means of determining the exact local time (and consequently his true longitude), no rules to guide him in keeping a great circle course from one given port to another. Similarly biologists and chemists are indebted to physicists and mathematicians for the perfection of their instruments; and such topics as heredity and Mendelism require for their full discussion a good deal of mathematics. Physiology, too, is becoming daily more dependent on physical theory and mathematical formulæ; for instance, a full explanation of the rise of sap in trees must involve a mathematical theory.

Such examples might be multiplied indefinitely. Let us now turn to another aspect of the question. Benjamin Disraeli, who was by no means the charlatan which some people suppose him to have been, is reported to have said that the best way of gauging the commercial prosperity of a country was to find out the condition of the chemical market. We may venture to assert that the intellectual state of a country may be estimated fairly well by its attitude towards mathematics and its progress therein. In this respect England is much inferior to other and smaller nations. For instance, in England many private libraries have been either given to the nation or placed at the disposal of genuine students: very few of these are wholly or mainly mathematical. Contrast with this the Mittag-Leffler endowment, of which an account will be found in Nature of July 6, 1916, p. 384. The founders expressly emphasised the supreme importance of pure mathematics from a national point of view. Again, no one can dispute the practical efficiency of the American nation; compare their treatment of mathematical professors with ours. An American university teacher may be a specialist devoted to the most abstract and "unpractical" parts of his science; he is left perfectly free to pursue his researches; he is provided with a sufficient staff of assistants; the university library contains an ample store of mathematical books, and all other necessary equipment is supplied. Every seventh year the professor is relieved of his official duties; and the use which he generally makes of his respite may be illustrated by the "History of the Theory of Numbers" (now in course of publication), by Prof. L. E. Dickson. His special subject is the highly abstract one of group-theory: but he spent his sabbatical year in ransacking the libraries of Europe, as well as of the United States, for works on the higher arithmetic. The result is an extraordinary display of laborious and accurate research: the first volume alone contains summaries, almost all of them based upon the author's personal examination, of thousands of papers. The value of the work, when complete, can scarcely be overestimated.

Finally, it is dangerous to neglect mathematics in schemes for a course of general education. From a school teacher's point of view the subject naturally falls into two divisions: (*a*) computation, drawing (including graphs), mensuration, and surveying; and (*b*) the theoretical treatment of the elementary parts of the subject. No attempt should be made at premature specialisation; the needs of the exceptionally gifted pupils may be met by giving them free access (with occasional advice as to choice) to the school library, which should contain books beyond the scope of the school course, and also biographies of mathematicians and works on the history of the subject. The main results to be desired, in the case of an average student, are these, among others: at the end of his course he should have a correct idea of the importance of mathematics and some acquaintance with its aims and methods, whatever his actual acquirements may be. Above all, he should have acquired the habit of intellectual honesty. A mistake in a mathematical exercise cannot be concealed by fudge, or argued about, as in the case of a historical essay or the like.

It is most disheartening to find that an organised attempt is being made to restore the study of Greek and Latin to its old position of prestige; fortunately, a number of eminent classical scholars have taken up a reasonable attitude, so that the danger may not be so great as it seems. Moreover, the report already alluded to should convince everyone that even with regard to the humanities it is not Latin-Greek but English that should be made the principal subject in English schools. The great Greek writers had not been condemned, in their school days, to wearisome lessons in Arabic or Hieroglyphics, although everything now argued in favour of Latin-Greek might have been urged equally well in favour of such preposterous procedure.

G. B. M.

Applications of the Thermionic Valve.[1]

By J. JOSEPH.

THE control of energy at distances of thousands of miles without any other medium than the æther has been made possible by the evolution of the thermionic valve. This remarkable invention can be described briefly as a highly exhausted glass bulb, in which is mounted a tungsten or tantalum filament heated by a battery giving about 6 volts. Electrons are emitted by the heated filament. The filament is surrounded by a grid or gauze cylinder, which is insulated and kept at the negative potential of the filament, while a plate of metal mounted inside the bulb is kept at a high potential of from fifty to several hundred volts by means of a battery or some other source of continuous current. The bulb is highly exhausted, and while the grid is kept at a normal negative potential, steady current passes from the filament to the plate or anode, but as soon as the grid is made slightly positive or negative, the current passing between the filament and anode by virtue of the electronic conductivity is increased or decreased. A valve can be used as a rectifier, as it can be made unilateral in conductivity by suitable adjustments of "grid potential." It can also be regarded as an inertialess relay, it being only necessary for the grid to be affected by the most minute change of potential for the valve to become more or less conductive, when it may be used indirectly to close a circuit and control magnetic or electrical operations.

One of the most important applications of the valve is the amplification of telephone currents in long-distance telephone trunk lines. Here, owing to the length of the cable and to the electrical constants involved, speech becomes greatly attenuated, and thermionic relays or repeaters are introduced about every thirty miles which amplify the speech to its original degree of loudness. In addition, cable of much smaller diameter and weight can be employed, as currents producing almost inaudible sounds can be amplified to any degree of strength. The introduction of these valve relays has effected a saving of thousands of pounds in many of our trunk telephone lines.

Another recent application of the valve is the magnification of the sound of the heart-beat. This is effected by means of a special transmitter, which rests by its own weight over the heart of the patient under examination. The heart creates vibrations in an air-chamber which reproduce exactly the complex action of the blood when passing through the valves of the heart. When connected to a thermionic valve amplifier and a special receiver attached to a large horn, the beat of the heart can be made audible to a number of people in a lecture-room.

The valve has also been used for the simultaneous reproduction of speech with the projection of a film on a screen, both picture and sound vibrations being photographed simultaneously on the same film, thereby ensuring perfect synchronisation. The vibrations of the voice are, by means of microphones, made to agitate a small mirror fitted on the camera adaptor, and a shaft of light passes from the mirror through a narrow slit. As the mirror vibrates, the band of light is reflected at constantly changing angles, and a wave form is produced which corresponds to the vocal sounds of the person speaking, as in the oscillograph. The wave form appears on the side of the film and is reconverted into sounds by means of a selenium cell, which, as is well known, possesses the peculiar property of resisting the passage of electricity in proportion to the intensity of light to which it is subjected. The variations in resistance caused by the passage of the film through the cinematograph are amplified by thermionic valves and made audible through a loud-speaking telephone. There are wide possibilities in this application of the valve.

An important feature of the valve is its great adaptability to the production of sounds of any frequency from one to many millions per second. A valve can be made to generate oscillations if the grid and anode are coupled to coils so as to form a transformer, the circuit of the coils being completed through a battery of 150 volts or more. By connecting a condenser across the anode coil, oscillations are set up, the frequency of which depends on the capacity of the condenser. If a third coil is coupled magnetically to the anode circuit, a note will be emitted corresponding to the frequency of the circuit, and by varying the capacity of the condenser, a wide range of frequencies can be generated for various testing purposes. The note emitted by the receiver is very clear and sharp, and the ease and rapidity with which the frequency can be changed renders the method particularly suitable for aural surgery, where frequencies covering a range of 200 to 3000 are often required. It is well known to aural specialists that certain people have what is known as a silent zone at particular frequencies. For instance, a patient's hearing might be normal for frequencies 200-500 and although he is deaf to frequencies 500-520. The aural appliances at present in use are not suitable for the rapid and accurate production of frequencies of any desired value. With a thermionic generator and a calibration chart, however, the frequency can be varied at will, and if a telephone head-receiver is worn by the patient and connected in series with a variable air condenser and the output or coupling coil, it can be determined readily what frequencies are inaudible to the patient. Further, by varying the capacity of the condenser the sound can be reduced gradually to inaudibility and, by calibration, a scale obtained which will give positions for normal hearing, imperfect hearing, and so on. By this means the effect of treatment can be determined to a very fine degree.

The human ear will not easily respond to frequencies greater than 3000 per second, although frequencies of 18,000 can be detected and instances have been known where 30,000 to 40,000 have also been heard. The frequencies used in wireless telegraphy are governed by the wave-length, and values of 500,000 per second, which correspond to a wave-length of 600 metres, are quite common. In spark telegraphy, the wave trains are

[1] Substance of a contribution to a discussion at the Institution of Electrical Engineers on March 6.

cut up into groups which are rendered audible to the wireless operator by means of a telephone receiver, which gives a click for every wave train, the signal being, of course, first rectified by the valve, so that a succession of musical sounds are heard in the telephone receiver corresponding to the Morse alphabet. The intermediate or high frequencies in each wave train are beyond human audibility, and are therefore not heard. The wave generated by the valve is, however, a continuous one, that is to say, every time the sending key is pressed a group of continuous waves are sent out at a frequency determined by the wave-length. To render them audible in the telephone at the receiving end, a local valve oscillator is used for generating frequencies slightly lower or higher than the received signal and, by heterodyning or superimposing one on the other, a frequency equal to the difference of the two notes is heard in the telephone receiver. This allows of exceedingly fine tuning, for the frequency of the local generator being under the control of the receiving operator, the difference in pitch is adjusted to 1000 cycles, the best value for human reception. It will therefore be seen that frequencies of as low as 1 can readily be detected, although, when the difference becomes very small, there is a tendency for one oscillator to pull the other into step.

Probably, the most interesting application of the thermionic valve is its use in radio-telephony. Here the valve is used to generate continuous waves in a suitable circuit and, by means of a microphone, the voice of the speaker is made to vary the amplitude of this wave at the different audible frequencies which are used in speech formation. These modulations are then conveyed to the aerial, and the telephone diaphragms at the receiving end are correspondingly stimulated and reproduce the speech exactly as transmitted. Numerous other uses have been found for the thermionic valve, among which may be mentioned direction finding, the navigation of aeroplanes in flight, its use as a rectifier for charging batteries, communication between moving trains, and the control of energy at great distances. In the latter direction mention may be made of communication by radiotelephony having been definitely established between England and Australia. Wherever a succession of signals can be received, they can always be amplified and made to operate selective electrical or mechanical relays for controlling power of any magnitude. The future holds a wonderful vision of vast operations at one end of the earth, being controlled by mankind at the other without any other medium than the æther.

Obituary.

Prof. Philippe A. Guye.

By the death of Prof. Philippe Auguste Guye, on March 27, Switzerland loses one of the most eminent of her savants, and the world of science is the poorer by the passing away, in the full maturity of his intellectual powers, of an assiduous and successful cultivator of natural philosophy, distinguished alike for the range and profundity of his knowledge, the force of his genius, his originality, his ingenuity and remarkable experimental skill. Geneva has long been a home of science; some of her citizens are among the most honoured of its votaries, and Guye now assumes his due position on a roll already made illustrious by the names of Saussure, De La Rive, and Marignac.

Philippe A. Guye was born at Saint-Christophe (Vaud) on June 12, 1862. His earliest scientific studies were made at the University of Geneva, where he worked under Graebe, with whom he published papers on diphthalyl and on naphthalene hydrides—a modest enough theme for the 'prentice hand—mainly a repetition of Graebe's observations of ten years previously, which seemed to have been called in question by the subsequent work of Agrestini. After taking his doctorate he repaired to Paris, where he remained some years, working in the laboratory of Friedel. Here he appears to have come under the influence of ideas on spatial chemistry which science owes to Le Bel, and much of his work during the next few years was devoted to their development. In 1892 he was recalled to Geneva to occupy the chair of theoretical and applied chemistry in the university of that city, to which he remained attached for thirty years. During this period Guye, by his energy and personal influence, his organising power, and the catholicity of his scientific aims, made an indelible impression on the academic life and activities of the university. He surrounded himself with a body of earnest and enthusiastic workers, attracted from all parts of the world, to whom he gave freely from a wealth of ideas which ranged over every department of chemical and physical science. It is estimated that upwards of 600 communications emanated from the Geneva laboratory while under his direction, some 200 of which bore his own name alone, many others being joint contributions by himself and his pupils. His own work was characterised by a rigorous sense of accuracy, by caution and a recognition of possible sources of error, amounting almost to intuition, combined with a capacity for generalisation and a *flair* for fruitful hypothesis which seemed, at times, like divination.

Although Guye began his scientific life under the guidance of Graebe, and at a time when the theory of organic chemistry and its technical applications were developing with extraordinary rapidity and success, systematic organic chemistry of the type with which the name of his eminent teacher is associated had few attractions for him, and it is doubtful whether Graebe's teaching and example had any permanent influence on his career. At all events, on his election to the Geneva chair he embarked upon the long series of investigations on problems of physical chemistry on which his fame mainly rests. He was early attracted to the many issues to which the molecular theory of Van der Waals gave rise. He discovered a series of new relations between the physical constants of liquids and their molecular magnitudes, and he greatly

extended the conception of molecular association in liquids. He devised new methods of determining the molecular weights of substances in the liquid state and at the critical point. He attacked the study of molecular dissymmetry, and traced the connection between optical activity and homology in liquids, between isomerism of position and rotatory power, and with the aid of his pupils he accumulated a great mass of experimental material which served to extend and substantiate his generalisations.

In 1903 Guye turned his attention to the study of atomic weights, and, in particular, to a critical examination of the experimental basis upon which these magnitudes rest. He thereby followed and perpetuated a tradition with which the fame of the Geneva school of chemistry, as personified by Marignac, will always be connected. Practically the greater number of the 100 contributions to the literature of chemistry which we owe to Guye's pen during the past twenty years are devoted to this subject, upon which he lavished all the powers of his matured intelligence, his experience, ingenuity, and manipulative skill. Thanks to his organising capacity and the ability and enthusiasm of his collaborators, we have been furnished with a series of fiduciary values which are probably among the best determined of physical constants, in which every known source of error has been rigorously scrutinised, and, so far as possible, eliminated. Naturally the trend of modern developments of ideas concerning the essential nature of the elements, and their fundamental relations and possible interdependence, attracted Guye's alert intelligence, and at the Brussels meeting of the International Conference in June last he pointed out their significance in connection with the proposed reorganisation of the work of the International Committee on Atomic Weights, of which he was an enthusiastic advocate, and on which, had he lived, he would certainly have made his influence felt as a member.

It might be supposed from Guye's mental characteristics, and from the nature of his studies, that he would have little sympathy with the technical applications of chemistry. No such surmise could be further from the truth. Although not a professed technologist, he had a considerable knowledge of manufacturing chemistry, and he enjoyed the confidence and esteem of the leaders of chemical industry throughout Switzerland, to whom he was always accessible, and by whom his counsel and advice were highly appreciated. His name will always be associated with the extraordinary development of electrochemical synthesis in Switzerland, to which his lectures and writings largely contributed.

Guye exercised great influence in scientific circles in Geneva, and took a leading part in the organisation of Swiss science. He presided over the Swiss Physical and Natural History Society, was a member of the central Committee of the Helvetic Society of Natural Sciences, and president of the Swiss Chemical Society and of the Council of Swiss Chemistry. In 1903 he established the *Journal de Chimie physique*, in which the greater number of the communications from his laboratory after that year were published, and he was mainly instrumental in placing *Helvetica Chimica Acta*—now the leading chemical journal in Switzerland—upon a sound and permanent foundation.

Guye's merits as a man of science were widely recognised. He was a member of the Scientific Academies of Petrograd, Madrid, and Bucharest, an honorary member of the Chemical Societies of France and England, a corresponding member of the French Institute, and a foreign associate of the Reale Accademia dei Lincei, and he shares with his countryman Marignac the honour of being a Davy medallist of the Royal Society. To the great regret of his many friends in England, the illness which ended in his death prevented him from coming to London to receive the medal in person.

He has another association with the memory of Davy, who died at Geneva, which British chemists will not forget. They are grateful to Guye for his pious care of the tomb which holds the remains of the great chemist.

T. E. THORPE.

PROF. W. B. BOTTOMLEY.

PROF. WILLIAM B. BOTTOMLEY, Emeritus Professor of Botany at King's College, University of London, died at Huddersfield on March 24, aged 58, after a long and trying illness which began in April 1918 with a seizure resulting from thrombosis. During the four succeeding years these seizures returned at intervals until the end.

Prof. Bottomley was born at Apperley Bridge, Leeds, on December 26, 1863, and was educated at the Royal Grammar School, Lancaster, and at King's College, Cambridge. He then studied at Heidelberg, where he received the Ph.D. degree. He was lecturer in biology at St. Mary's Hospital from 1886 to 1891. In the latter year he was appointed professor of biology at the Royal Veterinary College, and at the same time served as assistant in botany to Prof. Oliver at University College, London, and as a Cambridge University Extension lecturer. In 1893 he was appointed to the professorship of botany at King's College, London, which post he held until his resignation in 1920.

In 1905 Prof. Bottomley made a journey round the world in connection with University Extension work. He did a great deal of extra-mural lecturing under various auspices, and was well known as an excellent lecturer before either a scientific or a popular audience.

Prof. Bottomley's chief scientific interests were in connection with plant nutrition and the relation of these problems to agriculture. Towards the end of the nineteenth century he actively concerned himself with various co-operative agricultural movements, such as the Agricultural Banks Association and the English Land Colonisation Society. He was a man of great enthusiasms, and it is much to be regretted that he was unable to complete the important work with which his investigations were concerned. His name will always find a place in the history of plant nutrition, along with those of Boussingault, Lawes, and others. His most important contribution to the subject of plant nutrition was probably the discovery of what he called auximones, or growth-promoting substances, in materials such as peat which had been subjected to the action of nitrifying bacteria. The acidity of the raw peat had first to be neutralised by the action of ammonifying organisms. Experiments at Kew and the Imperial

College of Science, as well as King's College, showed that a striking increase in growth occurred when small amounts of this bacterised peat were added to the soil. This led to the chemical fractionation of such treated peat, the extract being used to test the stimulus to growth of the aquatic plant Lemna, and other plants, in culture solutions. It was found that 368 parts per million added to the culture solution gave in six weeks an increase in weight of 62 times the control plants. Other equally remarkable results were obtained. Various papers on the subject were published in Proc. Roy. Soc. and the *Annals of Botany*.

The method was patented, and in the early years of the war great hopes were entertained that peat deposits in many parts of the world could thus be made of direct service in stimulating food crop production. The controversies to which this commercialising of the process led, together with the loss of a son in the war, no doubt contributed to Prof. Bottomley's subsequent breakdown.

The discovery of auximones will remain a landmark in the long history of plant nutrition. These substances differ from vitamines in that they will withstand a temperature of 150° C., while the latter are largely destroyed by boiling. Moreover, unlike vitamines, auximones apparently have no effect on animals. They are probably derivatives of nucleic acid, and appear to be generated in soils through the activity of soil bacteria. Their presence indicates that these bacteria stand in somewhat the same relation to plants that plants do to animals; for the auximones appear to be bacterial products stimulating plant growth, while the vitamines are plant products which are essential for healthy animal development.

It is greatly to be hoped that these remarkable growth-stimulating substances can be isolated, their composition determined, and the method of their production standardised. They would then be of the utmost value to agriculture.

Prof. Bottomley was a member of the Council of the Royal Botanic Society, Regent's Park, where some of his experiments were carried out. He leaves a widow and two sons at Huddersfield, where the family removed from Hampstead a few months before his death.

R. R. G.

Dr. H. N. Dickson, C.B.E.

Henry Newton Dickson, born in Edinburgh in 1866, studied at the University of Edinburgh and came under the influence of the remarkable activities in experimental physics, meteorology, and oceanography directed by P. G. Tait and G. Chrystal in the University and by A. Buchan and John Murray outside. Like many other Edinburgh students of the later 'eighties of the last century Dickson seized the opportunity of acting as volunteer assistant in the work of the *Challenger* Commission, the Scottish Marine Station, and the Ben Nevis Observatory, and by this practical training in physiography he was fitted to take up the reviving study of geography on a basis of sound physical science. Thus, while his researches dealt exclusively with the special fields of meteorology and oceanography, his appointments were mainly in the teaching or the application of geography in its wider aspects.

In 1891 Dickson was engaged at the Marine Biological Association's laboratory at Plymouth in investigations on the salinity and temperature of the English Channel, and on his removal to Oxford in 1893 he extended this work to the whole surface of the North Atlantic. The water-samples were obtained by the officers of Atlantic liners and analysed by Dickson in the University chemical laboratory. It took several years to bring the methods of collection and discussion to perfection, and finally, with the co-operation of the Meteorological Office, Dickson produced his most important work, "The Circulation of the Surface Waters of the North Atlantic Ocean," which appeared in the Philosophical Transactions for 1901, and included monthly maps of temperature and salinity for the two complete years 1896 and 1897. This won him the Oxford D.Sc. degree in physical geography.

At Oxford Dickson joined the lecturing staff of the School of Geography and was very successful as a teacher. He moved to Reading in 1906, where he acted as professor of geography in the University College until 1920. During the war he gave practically his whole time to work at the Intelligence Division of the Naval Staff, where, amongst other duties, he undertook the preparation of an important series of handbooks descriptive of regions in which military operations were being carried on or where they might occur. For this he was decorated with the C.B.E.

In 1893 Dr. Dickson published a small volume on "Elementary Meteorology," which showed originality in conception and presented the principles of weather study in a very attractive form. This was followed in 1912 by a little book on "Climate and Weather," which was equally happy. He also wrote a book on "Maps and Map Reading." Dickson devoted much time to the study of underground water in the chalk formations near London, and the outbreak of war interrupted a most important investigation on which he was engaged with regard to the evaporation from an exposed water-surface. For this purpose he devised an automatic recording evaporimeter, which, so far as can be ascertained, was never made available for general use.

For many years Dr. Dickson was regular in attending the meetings of the British Association, acting as Secretary and Recorder of Section E, and in 1913 he was President of the Section. He was also a member of Council of the Royal Meteorological Society for many years and was President of the Society for 1911–1912.

His last work was in the Editorial Department of the additional volumes of the "Encyclopædia Britannica" for the 12th edition. Into this, as into all his other work, he threw his whole heart, and probably the most remarkable feature of his character was his indefatigable energy in whatever he undertook. He was married in 1891, and leaves a widow, a son in the Royal Navy, and a daughter.

H. R. M.

We much regret to learn from the Lister Institute that Mr. A. W. Bacot, head of the department of entomology, died at Cairo from typhus on April 12.

Current Topics and Events.

No British statesman of our times is more closely associated with scientific activities, or has done more to promote scientific interests, than Sir Arthur Balfour, upon whom the King conferred the honour of knighthood a few weeks ago and invested him with the insignia of the Order of the Garter. We notice, therefore, with much satisfaction the announcement that the King has been pleased to approve that the dignity of an Earldom of the United Kingdom be conferred upon him. Sir Arthur Balfour was elected a fellow of the Royal Society in 1888 and was president of the British Association at the Cambridge meeting in 1904. He has been Lord Rector of St. Andrews University and of Glasgow University, is Chancellor of Edinburgh University, and in 1919 he succeeded his brother-in-law, the late Lord Rayleigh, as Chancellor of Cambridge University. He is president of the British Academy, and Lord President of the Council, and by the latter office is concerned with the Department of Scientific and Industrial Research, in the work of which he takes active interest. Sir Arthur Balfour possesses a sure faith that no attempt to acquire and improve knowledge is vain, and a reasoned belief in the power of science to help and elevate mankind. He is a peer among philosophers and a trusted leader among statesmen, and the honour which has now been conferred upon him has given particular pleasure to all who work for social, intellectual, and scientific progress.

THE retirement is announced of Sir I. Bayley Balfour, Regius Keeper of the Botanic Garden at Edinburgh, Regius Professor of Botany in the University there, and King's Botanist for Scotland. Sir Bayley Balfour succeeded Dickson as Regius Keeper in 1888 and soon initiated that enlightened policy of friendly co-operation between the Commissioners of Works and the Regius Keeper which prevailed throughout his tenure of office. He placed the garden in the unique position it occupies to-day, and made it fruitful of result to botany and horticulture. His strength as Regius Keeper lay in more than one direction, and we may safely place his lovable human qualities and his knowledge of men in the centre of the arch, with his broad-minded, scientific outlook on one side and practical knowledge of horticulture on the other. As an administrator, his knowledge of men and affairs was never exhibited to better purpose than in the happy relations he established with one after the other of a succession of official chiefs who rightly trusted him implicitly. It is scarcely necessary in these columns to refer to Sir Bayley Balfour's position as a scientific botanist, but there is still much for him to do along lines of research he has made peculiarly his own, such, for example, as the differentiation of the great Rhododendron genus, by the characters of the leaf indumentum. As a practical horticulturist, he stands alone in the profundity of his knowledge of plants and their ways. Of late years, taking up the work where Franchet left it in 1900, he has taken the leading part in this country in the enumeration of the discoveries which have been going on for 40 years in the flora of the Western Chinese Alps, and which, in Rhododendron alone, far transcend the epoch-making results of Hooker's exploration of the Eastern Himalaya in the 'fifties. The consideration of the material already to hand, in the discovery of which George Forrest, an old member of the Edinburgh garden staff, has latterly played a major part, has resulted in the publication of a series of invaluable monographic "Notes" on Rhododendron, as well as Nomocharis, Chinese Gentian and Primula, all couched in the lucid style with which many previous publications of Sir Bayley Balfour's have made us familiar.

THE King, on the recommendation of the Secretary for Scotland, has approved the appointment of Mr. W. W. Smith to succeed Sir I. Bayley Balfour as Regius professor of botany in the University of Edinburgh, Regius Keeper of the Royal Botanic Garden, Edinburgh, and King's Botanist in Scotland. Mr. Smith has been assistant to the Regius Keeper for several years.

SIR HUMPHRY ROLLESTON has been elected president of the Royal College of Physicians of London.

SIR F. W. DUKE, Under-Secretary of State for India; Sir Berkeley G. A. Moynihan, professor of clinical surgery, University of Leeds; and Sir Ronald Ross, have been elected members of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public services."

THE latest news from the Mount Everest expedition reports an uneventful march from Darjeeling through Sikkim and over the Jelepla pass into Tibet. The road then lay along the Chumbi valley to Phari Dzong, to which place stores and grain had been despatched in advance. Gen. Bruce reports that on April 8 the expedition left Phari Dzong for Khimbajong. A message from the Pope wishing the expedition success was received before leaving Darjeeling.

ON Tuesday next, April 25, Sir Arthur Keith will begin a course of three lectures at the Royal Institution on "Anthropological Problems of the British Empire." Series II. "Racial Problems of Africa"; on Thursday, April 27, Prof. E. H. Barton will deliver the first of two lectures on (I.) "The Resonance Theory of Audition," (II.) "A Syntonic Hypothesis of Colour Vision"; and on Wednesday, April 26, and Saturday, May 6, Prof. D. H. MacGregor will deliver two lectures on "Industrial Relationships"—(I.) "The Historical Interpretation," (II.) "The Problem of Structure." The Friday evening discourse on April 28 will be delivered by Dr. Arthur Harden on "Vitamin Problems," and on May 5 by Dr. M. Grabham on "Biological Studies in Madeira."

THE special arrangements for Easter made by the French Physical Society include an address by Prof.

P. Weiss on the Strasbourg Physics Institute on Wednesday, April 19, and one by Sir E. Rutherford on the artificial disintegration of the elements on the following day, both delivered in the physics theatre of the science faculty of the University of Paris. On Friday a visit is to be paid to the new wireless station at Sainte Assise where the 2-kilowatt Paris-London station will be seen in operation; the continental 100-kilowatt station is just about to begin work, and a transcontinental station of 1500 kilowatts is being constructed. On the Thursday and Friday there will be an exhibition of apparatus at the rooms of the Society. At this exhibition British scientific apparatus makers have a joint exhibit. A number of French instruments not well known in this country will be displayed, as for example the Yvon spectrophotometer, a direct-reading micro-balance, and several wireless telegraphic appliances.

The second triennial meeting of the Astronomical Union will be held at Rome on May 2–10. The opening address by the president, M. Baillaud, will be delivered at 3 P.M. on May 2, at the Reale Accademia dei Lincei. The following are some of the proposals on the agenda paper: to make simultaneous observations of the variation of solar radiation, including the ultra-violet rays; to endeavour to expedite the completion of the astrographic catalogue; to organise observations of stellar parallax; to open a variable-star bureau at Lyons in collaboration with that at Harvard; to use plates sensitised for the infra-red in order to extend the spectral range and possibly to discover stars hitherto invisible; to organise the re-reduction of older star-catalogues, with a view to proper-motion determinations; to make arrangements for observing the near approach of Eros in 1931; and calendar reform. The Municipality of Rome will receive the delegates on May 4 and they are invited to Florence at the close of the meeting. Visits to Messina, Stromboli, and Etna have also been arranged. Prof. A. Fowler, Royal College of Science, South Kensington, is the General Secretary, and it may be mentioned that Messrs. Cook have arranged on favourable terms for a party leaving London on April 29, and returning on May 13.

The council of the Institution of Civil Engineers has made the following awards for papers read and discussed during the session 1921–22: Telford Medals to Sir Henry Fowler (Derby), Mr. H. N. Gresley (Doncaster), and Dr. H. F. Parshall (London); a Watt Medal to Mr. W. Willox (London); an Indian Premium to Mr. F. G. Royal-Dawson (London); Telford Premiums to Mr. A. W. Rendell (Bournemouth), Mr. W. F. Stanton (Chile), and Mr. A. C. Walsh (Chile). The council has also made the following awards for papers printed without discussion in the Proceedings for the session 1920–21: A George Stephenson Medal to Mr. J. H. Taylor (Buenos Aires); Telford Premiums to Mr. F. H. Hummel (Belfast), Mr. E. J. Finnan (Belfast), and Dr. Herbert Chatley (China); and a Trevithick Premium to Mr. G. E. Lillie (Reigate).

A paper by Sir Robert Hadfield, communicated to the Institution of Civil Engineers on April 4, represents the beginning of a very extensive and important research on the corrosion of ferrous metals which forms part of an inquiry, undertaken by the Institution in 1916, into the deterioration of structures exposed to sea action. It is proposed to place a large number of specimens of iron and steel, 1330 in all, in positions in which they will be exposed to the action of sea water under certain definite conditions. The present paper describes the metals selected for these tests, and gives full particulars of their mechanical properties, chemical analysis, and microstructure. In such an elaborate investigation it is obvious that every care should be taken to determine the exact conditions under which a test is made, and with this object in view special efforts have been made to define the properties of the test-pieces as accurately as possible. The materials selected include pure varieties of iron (wrought and Armco irons), mild and medium carbon steels of several kinds, steels containing copper, nickel, or chromium as a means of lessening corrosion, and cast irons. An ingenious system of numbering has been adopted, so that specimens can be identified even in the case of considerable corrosion taking place. The actual tests will necessarily occupy a long time, and will be supplemented by laboratory investigations. The paper concludes with a review of some of the problems and theories of corrosion, and with an estimate of the annual wastage of iron-steel through corrosion. For the whole world this loss is estimated to be 29 million tons, and the cost, after making allowance for protection, to be in the neighbourhood of 700 millions sterling.

In the March issue of *British Birds* the editor, Mr. H. F. Witherby, gives an account of the progress of the bird-marking scheme during the year 1921. The number of birds "ringed" during the period was 8997, the greatest total for any year since 1914, and the grand total for the thirteen years of the inquiry has reached the remarkable figure of 105,435. The best figures for individual species are those for the black-headed gull and the song-thrush, of each of which more than 11,000 have been marked since the inquiry began. The whole represents a noteworthy achievement, on which Mr. Witherby and his co-operators are greatly to be congratulated, and further important contributions to our knowledge of bird-migration are certain to result from the continuance of the work on this scale. Reference is made by Mr. Witherby to a useful discussion which has recently been going on in the pages of the magazine as to the future development of the inquiry. On the one hand, there are arguments in favour of concentration of effort: larger numbers of certain of the more interesting and "remunerative" species might be marked, and the results would be augmented in value if there were large series of recovery records relating to homogeneous or comparable marking groups. On the other, the opportunities presenting themselves to the majority of co-operators in the inquiry are for promiscuous marking, and these markers might merely be hampered by any attempt at restriction. An account of

some of the results of this inquiry was included in the article on "The Migration of British Swallows" in Nature of March 16.

The Ministry of Agriculture announces that bees can now be examined for the presence of the Acarine Disease on payment of a fee of 2s. for each sample submitted. Live bees only must be sent, and about 30 specimens should be taken from off the combs and packed in a small cage or box provided with ventilation-holes. A piece of muslin should be fastened across the inside for the bees to cling to during transit. A supply of candy sufficient to last for a few days, or a lump of sugar moistened with water, should be wrapped in muslin and fastened firmly to the inside of the box. The latter should be addressed to the Ministry of Agriculture, 4 Whitehall Place, London, S.W.1, and the name of the sender should be written on the reverse side of the label, but crossed through to prevent an error in transit. The remittance should be sent under a separate covering letter with as much information as possible concerning the bees. Payment must be made by postal order or cheque.

On March 22 at a meeting of the Institution of Aeronautical Engineers a paper was read by Mr. Manning on "Seaplane Design," and on March 31 Mr. H. P. Folland dealt with the subject of aircraft design generally. The programme of future fixtures includes papers by Captain Sayers on "Some Unsettled Problems of Aeroplane Design" and by Major Hume on "The Seaplane's Place in Aviation." Visits have been arranged to the works of the De Haviland Aircraft Company, Simms Motor Units Ltd., the National Physical Laboratory, the South Kensington Museum, and the Croydon Aerodrome. The secretary is Mr. L. Howard Flanders, 60 Chancery Lane, and the president, Col. J. T. C. Moore-Brabazon, M.P.

We have received from Messrs. Baird and Tatlock, of Cross Street, Hatton Garden, a copy of their new (1922) catalogue of apparatus for use in physiological and other laboratories where similar apparatus is required. The worker will find it a very valuable and an almost complete list of the instruments at present available for teaching and research purposes. In the latter case, it frequently happens that new apparatus has to be designed and fitted up to solve new problems; but the list sent to us will be of much assistance in giving information of what is actually to be obtained for the purpose in view. We note that the collaboration of physiologists has been obtained in the selection of the material to be included and the presence of apparatus for physico-chemical measurements is to be welcomed. The instruments for convenient measurement of electrical conductivity and potential have been somewhat difficult to obtain in recent years in England. The prices on the whole appear to be reasonable.

Our Astronomical Column.

The Shower of Lyrids.—These meteors may be expected to return on the night of April 21, and as the moon will be absent this year at the time of the maximum display, they should be well observed. The best hour at which to witness the event will probably be near midnight, for in the morning hours on April 22 the earth is likely to have passed through the denser part of the stream. The shower certainly lasts ten days, but it appears in its most active stage for a short period only. Of late years the meteors of this system have not been visible in striking abundance, and it is an unfortunate circumstance that its period of revolution is unknown. A brilliant exhibition of the meteors may occur in any year, and quite unexpectedly as in 1803 and 1851.

The Position of Neptune's Equator.—It has long been known that the plane of the orbit of Neptune's satellite Triton is changing its position. The only probable cause is the oblateness of Neptune, and it follows that the orbit plane makes a considerable angle with the planet's equator. By plotting out the poles of the satellite's orbit at different epochs we get an arc of a small circle, the centre of which is the pole of Neptune's equator. The latest determination of the position of the latter pole is that made by Mr. Arthur Newton (*Pop. Ast.*, March 1922). Making use of 1500 observations of the satellite, made from 1864 to 1908, he gives R.A. 19 h. 17 m., N. Decl. 38°·3 as the northern end of Neptune's axis. The pole of the satellite's orbit describes a circle round this, of radius 14°·7, in 425 years. There is little doubt that Neptune's rotation is retrograde; this has been verified for Uranus by the spectroscope, the period of $10\frac{3}{4}$ h. being found at the same time. In the case of Uranus the equator evidently coincides with the orbit planes, since these are all practically coincident and no change in them has been detected.

Determination of Star Magnitudes by a Thermopile.—J. Schilt has devised a new method of determining photographic star-magnitudes, which he describes in Bull. No. 10 of the Astr. Inst. of the Netherlands. The light and heat from a lamp are focussed by a lens on a small circle of the plate, which is somewhat larger than any of the star-images; these images are then moved in succession into the circle of light, and the amount of heat absorbed by the image is measured by the galvanometer of the thermopile. The process is rapid, the equilibrium temperature being attained in three seconds. The probable error, deduced by comparing the measures of two exposures on the same plate, is found to be 0·02 mag., whereas that from the method of diameter of image is 0·11 mag.

The most striking advantage of the new method is that it gets rid of practically all error due to variation in the shape of the image with varying distance from the centre of the plate. It also gets rid of the error that arises in the star diameters in plates taken with a refractor, due to the chromatic aberration which depends on the star's colour. In fact the method appears to give the integrated amount of darkening of the film independently of the size or shape of the image. This is verified by the application of the method to some of the polar plates taken with the 60-inch reflector at Mt. Wilson. The tables show that it gives good results up to a distance of 44 mm. from the centre of the plate, whereas Seares had found that the diameter method needed corrections of about half a magnitude at a distance of only 20 mm. The method would seem to have a large field of usefulness in the photometry of faint stars on reflector plates.

Research Items.

THE ICE AGE AND MAN.—In the January and April issues of *Man*, Messrs. H. J. E. Peake and J. Reid Moir have published schemes correlating the palæolithic types of culture with the geological strata. The conclusions proposed by both writers agree fairly, except that in Mr. Reid Moir's scheme the position of the Alpine glaciations has been moved up one stage. On this Mr. Peake remarks: "According to Mr. Reid Moir the Mousterian straddles the Riss, while Obermaier has argued with much force that it straddles the Würm, and the Magdalenian immediately precedes the Würm, while Penek and Schmidt have shown that this phase extended into the Bühl. This divergence seems to require some explanation."

RUSH AND STRAW CROSSES.—Rude bundles of straw or rushes, in the form of crosses, are often found hung over the doors in many parts of Ireland on St. Brigid's Day, the February festival marking the end of winter and the beginning of spring. Miss E. Andrews, who discusses the question in the April issue of *Man*, with a good illustration, suggests their connection in form with the Swastika, and infers that we have in them a very ancient symbol used in pagan times to represent the sun emerging from the darkness of winter. This ingenious explanation is supported by a certain amount of evidence, and it deserves consideration.

ANIMALS ON THE ROOF.—In the March number of *Folk-lore*, Prof. H. J. Rose of University College, Aberystwyth, attempts to explain a passage in Petronius where Trimalchio speaks of Asinus in Tegulis—the portent of an ass appearing on the tiles. He brings together a number of examples showing that in the lower culture the appearance of an animal or a bird on the roof is regarded as portentous. This leads to the consideration of the roof in connection with beliefs regarding the house. He suggests that in the case of Trimalchio's ass the animal may have been conceived as an evil spirit or a new and particularly disagreeable form of ghost. The uncanny effect of fire-light on the rude thatching and the smoke-wreaths, the strange scratchings and patterings of small nocturnal animals running over the top of the hut, nightmares in which the roof threatens to fall and crush the sleeper, real injuries from the collapse of the flimsy structure, the intrusion of beasts of prey, bats, moths, and small birds fluttering about inside—all these and many other factors may well have united to make up the sum of this curious chapter of folk-belief.

CYTOPLASMIC INCLUSIONS OF THE GERM-CELLS.—The discovery of the chromosomes and their behaviour both in ordinary cell-division and in the maturation of the germ-cells opened up a new era in the study of the mechanism of heredity, and it is now widely believed that the chromosomes are the bearers of "factors" or "genes" that are responsible for the transmission of heritable peculiarities. In recent years, however, a good deal of attention has been paid to certain structures, the "mitochondria" and "Golgi apparatus," that occur in the cytoplasm, outside the nucleus, and it has been suggested that the mitochondria, at any rate, may constitute the protoplasmic basis of heredity. In the current number of the *Quarterly Journal of Microscopical Science* (vol. 66, part 1) Prof. J. Brontë Gatenby concludes his notable series of memoirs on "The Cytoplasmic Inclusions of the Germ-cells," and expresses the opinion that "As direct bearers of any important or precise factors of heredity, the Golgi body and mitochondria appear to be ruled out by their inexact and variable behaviour in the germ-cell cycle. The chromosomes, and the chromosomes alone, fulfil the necessary conditions."

ENTERONEPHRIC EXCRETORY ORGANS IN EARTHWORMS.—A few years ago a remarkable "enteronephric" system of excretory organs in Pheretima was described by Dr. K. N. Bahl, consisting of modified nephridia which open by a system of ducts into the alimentary canal, instead of opening on the surface of the body as in the usual (integumentary) type. The system consists of septal and pharyngeal nephridia. It was a matter of considerable interest to determine whether these modified nephridia are formed from the epiblast of the embryo, like ordinary nephridia, or whether they develop in some other way. Dr. Bahl has now investigated this problem and gives in the *Quarterly Journal of Microscopical Science*, vol. 66, Part 1, a detailed embryological account of the organs in question, as well as of the integumentary nephridia of the same worm. He finds that all three types can be traced back to the original epiblastic row of nephridial cells. The connection of the enteronephric system with the alimentary canal is evidently a secondary feature that has arisen comparatively late in phylogeny.

THE EFFECT OF TEMPERATURE ON THE ABSORPTION SPECTRA OF GLASSES.—The observations of Houstoun on the absorption spectra of eight or nine kinds of coloured glass showed in 1906 that, while in most cases an increase of temperature from 15° C. to about 330° C. produced in the visible spectrum an increase in the absorption on the longer and a decrease on the shorter wave length side of an absorption band, this was not invariably the case. Nor was the absorption in all cases decreased by increase of temperature. Gibson in 1916 investigated five glasses at −180° C. and 430° C. in the visible part of the spectrum, and found in some cases, as for instance that of a red glass, that the absorption for a particular wave length increased at the higher temperature to fifty times its value at the lower. In a Ph.D. thesis of the University of Pennsylvania recently issued, Mr. G. Rosengarten describes his measurements of the absorption of a number of coloured glasses in the infra-red between wave lengths 1 and 5×10^{-4} cm. His source was a tungsten lamp, his spectrometer prism of rock salt, and the issuing radiation was measured by a thermo-pile. Up to 500° C. he finds the changes in absorption seldom exceed the instrumental error of 8 per cent.

COLOUR SENSITIVE PHOTOGRAPHIC PLATES.—We have received from the Bureau of Standards, Washington, a copy of a communication entitled "Studies in Colour Sensitive Photographic Plates and Methods of Sensitising by Bathing," by Francis M. Walters, Jr., and Raymond Davis. The authors describe their methods of investigation, and deal with pinacyanol in considerable detail. They have also investigated the use of dicyanin, erythrosin, pinaverdol, pinachrome, orthochrome T, and homocol, as well as the hypersensitising of commercial panchromatic plates. They find that the various dyes require different methods for their most successful application. The previous washing of the plate to be treated is sometimes of great importance, and the effects of alcohol and of ammonia need, perhaps, more attention than they have hitherto received. The paper is well illustrated. It is ready for distribution and any one interested may obtain a copy from the Bureau until the free stock is exhausted.

A Unique Long-period Variable Star.

By Major W. J. S. Lockyer.

SINCE the year 1811 the star designated R. Aquarii (position for 1900 Right Ascension $23^h\ 38{\cdot}6^m$, Declination $-15°\ 50'$) has been known as a variable star. It goes through a complete cycle of variability in 385·5 days, attaining a maximum brightness of 6·2 and a minimum of 11·0.

This star, like about 85 per cent. of all long-period variables, has a spectrum of the class Md, *i.e.* a spectrum showing bright hydrogen lines and numerous absorption flutings of titanium-oxide on a continuous spectrum, and indicative of comparatively low temperature.

Fig. 1.—Nebulosity around R. Aquarii.
Photographed by C. O. Lampland, Lowell Observatory.

On October 16, 1919, Mr. Paul W. Merrill, using the 100-inch reflecting telescope of the Mount Wilson Observatory, discovered that several other bright lines, characteristic of gaseous nebulæ, were present. This made the spectrum unique, because while there is considerable evidence to connect hot stars, such as Class O or Wolf-Rayet Stars, with gaseous nebulæ, there was no instance, prior to this, in which a comparatively cool star is associated with the nebulæ.

A further interesting observation that has been made is that while the nebular lines remain almost constant in intensity throughout the light changes of the star, the other lines representing the Md spectrum vary through a large range. This suggests that the star and nebula are independent of one another: other observations on the other hand tend to show a close connection between the two.

The most recent discovery relating to this star is of extreme importance, for it is now known that the star is in the centre of a mass of nebulous matter.

The photograph showing this was taken by Mr. C. O. Lampland with the 40-inch reflecting telescope of the Lowell Observatory. This nebular image he describes as an oval-shaped, elongated configuration composed of arcs of well-defined nebular filaments and the star is centrally and symmetrically placed. The position-angle of the longer axis of the formation is about 90° and the greatest extent of the faint structure in this direction is a little more than two minutes of arc. Mr. Lampland has forwarded a positive photograph on film from which the accompanying illustration (enlarged twice) has been made. On his photograph 1 mm. represented 24·5 seconds of arc (approx.).

The general form of the nebulosity here displayed is very similar to that of the nebula N.G.C. 5921. This latter is reproduced on Plate I. in vol. xiii. of the "Publications of the Lick Observatory," and is given there as an example of what Mr. H. D. Curtis calls a ϕ-Type Spiral Nebula.

The actual presence of this nebulosity is of great value in accounting for the unique character of the star's spectrum. Attention must also be directed to the importance of long-exposed photographs with powerful reflectors for the purpose of searching for nebulosities whenever nebular lines appear in a spectrum. It will be remembered how such lines, appearing in the spectra of novæ in the later stages of their career, led to the discovery of the presence of nebular matter surrounding the star.

Marine Invertebrates.

FURTHER reports on material collected by the British and Australian Antarctic Expeditions have been received. The Chætognatha of the Australian Expedition have been described by Prof. T. H. Johnston and Mr. B. B. Taylor, systematic accounts of the Crustacea of the British (*Terra Nova*) Expedition are given by Mr. R. W. Barney on the Ostracoda, and on the Tanaidacea and Isopoda by Dr. W. M. Tattersall. Dr. H. M. Woodcock and Miss Olive Lodge describe the collection of parasitic protozoa, which consists of only three species—a new species of the flagellate genus Cryptobia, a new species of Gregarine (Selenidium), and a ciliate. This ciliate, for which a new genus (Hæmatophagus) is created in the family Stentoridæ, is parasitic on the baleen plates of the humpback whale, and feeds exclusively on the whale's red-blood corpuscles. It reaches a length of 1-1·5 mm., and secretes a delicate transparent tube, up and down which it moves; when feeding the oral end of the ciliate may project from the tube. The red-blood corpuscles are directed into the mouth by the adoral zone of strong cilia fused into membranellæ, pass into the protoplasm, and become enclosed in food-vacuoles. The larger vacuoles may contain numerous corpuscles which become compressed, and, owing to the dissolution of the envelope of the corpuscles, the hæmoglobin-containing substance of all the red cells in the vacuole merges into one homogeneous mass. As digestion proceeds the vacuoles pass gradually backwards, and pigment—agreeing in appearance with melanin—is formed on the outside of the vacuole. Hæmatophagus is unique among ciliates in producing melanin as a result of the digestion of hæmoglobin. This pigment tends to accumulate in the hinder half of the body, and the authors find evidence that when the organism is full-grown the pigment is got rid of by casting off that portion of the body prior to the commencement of the resting, multiplicative phase. How the blood of the whale becomes available to the ciliate has not been established.

Mr. C. H. Edmondson gives (Occasional Papers, Museum of Polynesian Ethnology and Natural History, Honolulu, 1920) a short account of the edible mollusca of the Oregon coast. These are all bivalves; some, belonging to the genera Siliqua and Mya, are

known locally as "clams" of various kinds, and there also occur two species of Mytilus, a pecten, a cockle, and an oyster. The Indians made extensive use of these molluscs before the advent of the white man on this coast, as is shown by the great heaps of shells still remaining. *Mya arenaria*, which was transported from the Atlantic coast many years ago, probably with oyster-spat, has become well-established in many localities on the Pacific coast, where it inhabits the mudflats of bays and has advanced up some estuaries, always remaining, however, within the influence of salt water. The author records that in January, 1918, excessive rainfall caused exceedingly high water in one of these estuaries, the Mya being washed with comparatively fresh water for four weeks, and at the end of the period a dense layer of fine sand, up to 2 in. in depth, covered the clam bed. A high percentage of the younger and weaker individuals was found to be dead, probably smothered by the fine silt. Mya is found to withstand transportation to inland markets if kept at a low temperature, and will remain in good condition for a week after having been taken out of the water, but the other clams cannot be sent successfully any distance in marketable condition. Certain of them are canned at the coast. Observations are given on the spawning periods and growth of the bivalves.

The attention of students of recent Crinoids may be directed to a paper by Dr. Austin H. Clark on "Sea-lilies and Feather-stars" (Smithsonian Misc. Coll., vol. 72, No. 7, 1921). The account, while devoted chiefly to external and skeletal features, includes short notes on regeneration, asymmetry, distribution, food, locomotion, etc.

Water-power Resources of India.[1]

THE Triennial Report (1919–1921) of the Hydro-Electrical Survey of India, which has just been received, is of the character of a comprehensive volume, embodying all the essential information contained in the preliminary and second Reports, which have already been noticed in NATURE. In addition, it contains later information derived from the investigation of certain sites selected for their potential value as sources of water-power supply. In the result, the opinion is formed "as a rough preliminary forecast" that the probable water of India for maximum development is some 12,680,000 kilowatts, equivalent to 21½ million water horse power, of which only 1¼ per cent. so far is developed or in course of development. The estimate is, of course, to be received with caution, as it is largely "speculative and based on the minimum of reliable information." The water power actually developed at the present time amounts to 138,780 kw., (continuous), capable of being expanded to 213,150 kw., in accordance with the ultimate capacity of the sites exploited. The following is a detailed summary of the probable *minimum* continuous water power:—

	Kw.
Assam	414,000
Baroda	4,000
Bengal	669,850
Bihar and Orissa	62,550
Bombay	644,310
Burma	951,570
Central India	680
Central Provinces and Berar	137,560
Cochin	4,000
Coorg	1,500
Gwalior	43,300
Carry forward	2,933,320
Brought forward	2,933,320
Jammu and Kashmir	305,330
Madras	92,310
Mysore	48,500
North-West Frontier	1,000,000
Patiala	290
Punjab and Canals	793,150
Rajputana	160
Sikkim	5,000
Travancore	450
United Provinces and Canals	403,370
	5,581,880

The Survey is being made under the supervision of Mr. J. W. Meares, who was appointed Chief Engineer in succession to Mr. F. E. Bull. It is noteworthy that the same reluctance to finance hydrographical surveys exists in India as in other parts of the Empire. Mr. Meares is much concerned as to the outlook. As a consequence of the "Reforms" made by the Government of India, it was decided in October, 1920, that all outlay on water storage and water power would be a Provincial charge and that the necessary provision for hydro-electric surveys should therefore be made in the Provisional Estimates from and after the year 1921–22. When the Estimates came up for approval before the various legislative councils, in many instances reductions were moved, and as the matter now stands "the Survey is in danger of falling between the upper and the nether millstone, as the Government of India is no longer able to provide funds for a continuance of the work."

A considerable quantity of useful data is incorporated in the volume, including seven plates and maps, 23 diagrams, and 51 tables. Much detailed information is set out for the guidance and direction of those engaged in the Survey, of whose cordial co-operation Mr. Meares speaks very highly.

[1] Hydro-Electric Survey of India. Volume III. Triennial Report with a Preliminary Forecast of the Water Power Resources of India, 1919 to 1921. By J. W. Meares. Pp. ix+199. (Calcutta: Government Printing Office, 1921). 4 rupees.

University Pensions.

THE Sixteenth Annual Report of the Carnegie Foundation for the Advancement of Teaching provides some interesting reading, especially regarding pension systems. The claim is made that in the Reports of the Foundation will be found "the most complete information concerning pensions and pension systems in existence." The remarks on the University Teachers' pensions in England and Wales deserve notice. Reference is made to the movement of the Association of University Teachers to secure the extension of the School Teachers (Superannuation) Act of 1918 to University teachers, or failing this to obtain benefits at least equivalent to those offered by the Act. As in previous years, the Report shows a strong bias against any non-contributory scheme. It is very easy to understand why this should be so. The Teachers' Insurance and Annuity Association of America could not have come into existence on any other than a contributory basis. On its own showing the Foundation was unable to finance a scheme such as is growing up in America. But no attempt is made to demonstrate how such a contributory scheme can be "sounder" than a non-contributory scheme backed by the government of the country. It would

be difficult to do so in face of the existence of the British Civil Service, and the report wisely refrains from the attempt.

In regard to the "problem of transfer" the report is greatly at fault. It is a pity the writer of it did not seek more accurate sources of information or at least endeavour to understand the facts of the case. At the present moment, and for the future unless a change is made, a teacher who "transfers" to a university sacrifices superannuation benefits in whole or in part. This is acting adversely upon the recruiting of university staffs, and will continue so to act unless some attempt is made to obviate this loss. We can assure the writer that the question of transfer from the lower to the higher branches of the profession in this country is a really serious one, and one which is felt especially in the departments of science and technology, as well as in those for the training of teachers. For example, some schools of the University of London come under the Act and others under the Federated Superannuation System, two totally different schemes, and in consequence transfers from one college to another in one and the same university are difficult if not impossible.

It may interest American university teachers to know that the British Government has made a grant of half-a-million towards retrospective benefits ("accrued liabilities") for the senior members of the teaching staffs in the universities—a sum which, by the way, is quite inadequate for the purpose—but for some extraordinary reason has made no provision for retrospective benefits in regard to teaching service in institutions and schools outside the universities. Is there any better way of making watertight compartments of the various branches of the teaching profession?

University and Educational Intelligence.

Cambridge.—Close on the publication of the report of the Royal Commission commending the women's colleges to private benefactors comes the welcome announcement of a bequest to Girton College of 20,000*l*. This money, left by Rosalind, Countess of Carlisle, is earmarked for scholarships of 80*l*. per annum for girl students unable to pay for themselves.

London.—The following doctorates have been conferred:—Ph.D. (Science) on Mr. A. C. Chibnall, for a thesis entitled "The Distribution of Nitrogen in the Leaves of the Runner Bean"; Mr. T. J. Drakeley, for a thesis entitled "The Ultimate Composition of British Coal"; Mr. H. S. Hatfield, for a thesis entitled "On a New Method for the Separation of Mechanical Mixtures of Powdered Substances"; Mr. G. H. G. Plymen, for a thesis entitled "The Geology of Jersey and Alderney"; Thirza Redman, for a thesis entitled "Observations on (Experimental) Intestinal Tuberculosis"; Barbara Russel-Wells, for a thesis entitled "The Constitution of the Cell Wall in Plants, more particularly that of the Red Seaweeds"; and Mr. T. Thomas, for a thesis entitled "The Effect of Stress on the Thermo-Electric Properties of Metal Wires with and without a Magnetic Field."

At University College, Gower Street, W.C., a course of six lectures on the Early History of the Land Flora will be given by Dr. D. H. Scott at 5.15 p.m., on Wednesdays April 26 and May 3, 10, 17, 24, and 31. The lectures will be illustrated by lantern slides.

At King's College, Strand, a course of four lectures on Biological Aspects of Oceanography will be given by Dr. Johan Hjort (of the University of Christiania) at 5.30 p.m., on April 28, May 1, 2, and 5. The lectures will be delivered in English.

At Bedford College for Women, Regent's Park, a course of three lectures on "L'Intelligence et la Volonté" will be given by Prof. E. Claparède (professor of psychology in the University of Geneva) at 5.15 on April 28, May 1 and 2. The lectures will be delivered in French. Admission to all these lectures is free without ticket.

Two Munitions Committee Fellowships in research in engineering are offered by the University of Liverpool. The fellowships are tenable in the first place for one year, value 250*l*. each, but may be renewed for a second year when their value will be 350*l*. each. Forms of application and all particulars may be obtained from the Registrar of the University. Applications for the fellowships must be received before June 1.

Some interesting summaries are provided in *Science* of March 17 showing the number of doctorates in science conferred by American universities in the year 1920–1921, and their distribution according to subject. In all, 332 doctorates in science were conferred by 32 institutions, an increase of nine on the corrected figures for the previous year; with one exception, they were distributed over the same universities. In spite of the increase, the number still falls far short of the maximum, 372, recorded for 1917. As has been the case for several years past, the biggest number, 42, was awarded by the University of Chicago, though Cornell, Columbia, Yale, Harvard, California, and Johns Hopkins Universities all conferred more than 20 doctorates each. Chemistry has, since 1912, claimed a great many more doctorates than any other subject, and in 1921 it seems to have been more popular than ever; no less than 134 doctorates of the total of 332 were given for this subject while the next highest figure is 36, the number of doctorates awarded for zoology. Botany, physics, and psychology were each of them the subjects of the theses of 25 to 30 doctorates.

On Monday, April 24, Dr. Malinowski, the well-known Polish sociologist, will deliver at the London School of Economics the first of a course of eighteen lectures on "The Sociology and Economics of Some Island Communities." This course of lectures embodies the results of an investigation of four years' duration in the course of which Dr. Malinowski made an intensive study of the culture of the Papuo-Melanesian communities on the coastal mainland and on the archipelago around the eastern end of New Guinea and more particularly of those of the Trobriand Islands. The complex economic system, of which Dr. Malinowski has already given some account in a previous course, will be analysed, and the remarkable manner in which their intricate economic system permeates their whole life will be described. In this field of investigation, Dr. Malinowski's results were not only unexpected, but they threw an entirely new light upon certain elements in primitive life. In like manner his investigations have revealed a definite, though rudimentary, legal machinery for the preservation of law and order. The regulation of sex life by taboos has given rise to a mythical cycle and a whole system of love-magic; while sorcery, which plays a large part in the life of the native, is based upon a complex system of auto-suggestion and counter-suggestion. The most significant feature in the material which Dr. Malinowski has collected, is the extraordinary complexity and inter-relation of the elements of native life. On more than one occasion reference has been made to difficulties arising out of this complexity when native custom is modified under European authority. Dr. Malinowski's results, from this point of view, are a strong argument in favour of the institution of a central organisation at which such data as these may be made available for the use of administrators.

Calendar of Industrial Pioneers.

April 20, 1821. Franz Karl Achard died.—Descended from a French protestant family, Achard was born in Berlin, worked at chemistry with Marggraf and became director of the physical department of the Berlin Academy of Sciences. He was a pioneer in the production of sugar from beetroot and in 1801 erected a sugar factory.

April 21, 1819. Oliver Evans died.—Born in Newport, Delaware, in 1755, Evans became a practical miller. He was the author of numerous improvements in milling, and his system was adopted both in America and Europe. He also experimented with high-pressure steam; in 1803 he began building steam engines, and the same year constructed a self-propelling dredging machine.

April 21, 1889. Robert Stirling Newall died.—The inventor in 1840 of iron wire ropes, Newall established works at Gateshead and became famous as a maker of submarine telegraph cables. The first successful cable between Dover and Calais was made by him in 1851, and he constructed half of the first Atlantic cable. He was also known as an astronomer, and presented one of his large telescopes to the University of Cambridge.

April 22, 1833. Richard Trevithick died.—One of the greatest engineers and the most fertile inventors of his day, Trevithick, like Evans, turned his attention to the use of high-pressure steam, constructed double-acting high-pressure engines, and between 1797 and 1808 made important experiments with locomotives. The son of a manager of a mine, Trevithick became chief engineer of some of the mines in Cornwall. In 1813 he erected some of his engines in Peru, where he resided about ten years.

April 22, 1864. Joseph Gilbert Totten died.—Trained as a military engineer at the West Point Academy, Totten rose to be colonel of the Corps of Engineers of the United States, and became known for his researches on the strength of materials and allied subjects, his work on the lighthouse board, and his investigation of New York harbour.

April 23, 1897. Adam Hilger died.—The founder of a firm of scientific instrument makers, Hilger was a native of Darmstadt. After being trained as a mechanical engineer he worked under Ertel in Munich and under Lerebours in Paris and about 1870 came to England. A few years later he set up in business for himself at Islington, becoming well known as a constructor of instruments for celestial spectroscopy.

April 25, 1840. Sir Robert Seppings died.—Master Shipwright at Chatham Dockyard, and then from 1813 to 1832 Surveyor of the Navy, Seppings introduced improved methods of docking and undocking ships, and was the inventor of the system of diagonally bracing and trussing the frame timbers of ships, an innovation of the first importance. He gave an account of his improvements to the Royal Society and was awarded the Copley medal.

April 26, 1893. Edward Alfred Cowper died.—An apprentice of John Braithwaite, Cowper afterwards worked with Fox and Henderson, and was employed on the buildings for the Great Exhibition of 1851. He then became a consulting engineer and was known for his work in connection with the development of the compound steam engine, his invention of the regenerative hot blast stove, and the introduction in 1868 of the modern bicycle wheel with wire-spoke suspension. In 1880 he was elected President of the Institution of Mechanical Engineers.

E. C. S.

Societies and Academies.

LONDON.

Royal Society, April 6.—Sir Charles Sherrington, president, in the chair.—F. E. **Smith**: On an electromagnetic method for the measurement of the horizontal intensity of the earth's magnetic field. A Helmholtz-Gaugain arrangement of coils consisting of two interwoven helices of bare copper wire wound in spiral grooves in a marble cylinder are mounted on each side of the centre. Each coil is of 30 cm. radius, of six turns, and of $1\frac{5}{8}$ mm. pitch. The cylinder is mounted on a non-magnetic base, and can be rotated about a vertical axis. The magnet at the centre is 1 cm. long and about 6 sq. mm. in cross-section; it is supported on a V of aluminium foil by a fine quartz fibre, to which is attached a reflecting mirror and a damping vane. The magnet is easily removed from its support, and a copper wire of equal weight substituted. The axial magnetic field due to the current in the coils is made slightly greater than "H," and its component in the magnetic meridian opposes H. By adjustment of the angle α between the axis of the cylinder and the direction of magnetic north, the indicator magnet is caused to set at right angles to the meridian. When torsion is eliminated, $H = Fi \cos \alpha$, where F is constant of coil system and i is current. A determination of H occupies less than 4 minutes. The probable error, including that due to uncertainty of the value of the current, measured by a current balance, is about ± 4 in 100,000.—G. I. **Taylor**: Stability of a viscous liquid contained between two rotating cylinders. Steady motion of viscous liquid between two concentric rotating cylinders is unstable for symmetrical disturbances, provided the velocity of the system is greater than a certain value, and the ratio of angular velocities of the cylinders is less than the reciprocal of the square of the ratio of their radii, or is negative. The type of instability is periodic along the length of the cylinders, consisting of vortices enclosed in partitions rectangular in section, and they rotate alternately in opposite directions. When the cylinders rotate in the same direction each vortex extends across the space between the cylinders. The length occupied by each vortex is equal to the thickness of fluid between them. When the cylinders rotate in opposite directions, two systems of vortices rotating as though geared together appear. Some criteria for stability in approximate form suitable for numerical computation have been obtained.—T. H. **Havelock**: Dispersion formulæ and the polarisation of scattered light; with application to hydrogen. Simple types of dispersion formulæ are considered when the medium consists of anisotropic molecules distributed at random and having an axis of symmetry. A formula for the corresponding ratio of the intensities of the two polarised components of light scattered at right angles, when the primary light is unpolarised, is given. The case of hydrogen is examined numerically and the ratio of the intensities agrees substantially with Lord Rayleigh's experimental value.—G. R. **Goldsbrough**: The cause of Encke's division in Saturn's ring. A satellite will, from its inclined path alone, produce one new division in the ring system. If the satellite be Mimas, a narrow division closely corresponding to Encke's division is produced. Similarly, Enceladus should produce a division in Ring B, but it would be almost unobservable.—C. **Spearman**: Correlation between arrays in a table of correlations. Correlations between arrays are expressed as functions of the independent variable elements entering into the main variables. When only one element is common

to any different variables, then the correlation between every two parallel arrays amounts to plus or minus unity. The converse is also true. The correlational coefficients considered are derived from product moments and the proofs do not assume any "normal" frequency distributions.—W. L. **Balls**: Apparatus for determining the standard deviation mechanically. The apparatus is related to the "Harp" Harmonic Analyser, similarly utilising separately loaded strings to deflect a yoke upon which they all converge. The design of the yoke has been modified to make the readings quantitative, and each string is loaded in proportion to the square of its deviation from the zero position. A template representing the frequency curve under examination is inserted behind the loaded strings, and the movement of an optical lever gives the "sum of the squares of the deviations." The reading is then transferred to a monograph to complete the calculation. The values obtained are correct to within 5 per cent.

Association of Economic Biologists, March 31.—Prof. E. B. Poulton, president, in the chair.—W. Lawrence **Balls**: The advantages and disadvantages of team work in economic biology. An attempt to enunciate certain principles governing the increasing development of team work between different scientific workers and sciences, particularly on the industrial and economic side. Minor principles: (1) the team leader must administrate research, and not merely administrate; (2) the "scientific management" of scientific research must be considered; (3) every new problem needs a new method. Of major principles, apart from the self-evident essential of sincerity, two are enunciated: (1) The specialist in an applied science must be a "jack-of-all-trades"; (2) the scientific worker's code of "individualism in effort and credit; communism in results" must not be contravened.—F. **Kidd**: Problems of fruit storage. The uses of fruit storage in commerce were described and an outline given of the amounts of fruit imported into this country as compared with what is grown ourselves. Apples, more particularly, were dealt with as one of the most important crops and our backward position in relation to other countries with regard to apple storage pointed out. An account was given of experiments carried out to test the efficacy of gas storage, a cheaper method than cold storage, the possibility of which was first suggested by purely scientific work carried out by the author on the effect of carbon dioxide and oxygen upon germination and growth. Finally, the author dealt with a series of recent experiments upon the respiration of apples during their storage life after gathering. At each of three temperatures tested, 2·5° C., 10° C., and 22·5° C., the rate of respiration changes with age in similar manner, first rising, then falling. The age changes in the respiration curves are, however, not related to the amount of respiration. Apparently, while the respiration rate has a temperature relation of 1 : 2·5 : 8, the age factor has a temperature relation of the order of 1 : 4 : 30, and consequently at analogous points on the age respiration curves more carbon dioxide has been produced at 2·5° C. than at 10° C. or 22·5° C.

Zoological Society, April 4.—Prof. E. W. MacBride, vice-president, in the chair.—R. H. **Burne**: The recessus orbitalis in flat fishes.—L. T. **Hogben**: The influence of pituitary gland in inducing metamorphosis of the Axolotl.—J. T. **Cunningham**: Mendelian experiments on fowls. III. Production of dominant pile colour.—M. **Khalil**: A revision of the nematode parasites of elephants, with a description of four new species.

Linnean Society, April 6.—Mr. H. W. Monckton, vice-president, in the chair.—A. B. **Rendle**: A seedling of the red horse-chestnut (*Æsculus rubicunda*) in which a new terminal bud had been developed to replace the original shoot springing from the seed. The original main shoot, broken some distance below the plumule, was covered after a few days by a new growth which developed into a new terminal bud. The new bud resembled a normal terminal bud the outer leaves of which are imperfect.—L. A. **Borradaile**: The mouth-parts of the shore crab, *Carcinus mænas*. Each of the paired appendages plays a distinct part in manipulating the food. The circulation of the water in the gill-chamber follows a definite course dictated by the arrangement of the organs. The maxillipeds of the third pair of appendages function in feeding, as an operculum, and as cleaning organs.—C. **Turner**: The life-history of *Staurastrum Dickiei*, var. *parallelum* (Nordst.). The contents of the spores of this desmid were, at first, of an oily character. During later stages four nuclei were visible; this apparently indicates that conjugation resulted in a diploid nucleus, and that a reduction division occurred inside the spore before the discharge of its contents. Germination results in the formation of four, three, two, or one desmid only, usually accompanied by an atrophied nucleus in the surrounding protoplasm when the smaller numbers are formed. Conjugation is usually of the normal type, and the zygospores are produced between the two desmids; a conjugation tube was seen in one instance only. The conjugating desmids were asymmetrically placed and the protoplasmic contents indicate a slight differentiation of the sexes. The conjugation of a four-rayed with a three-rayed form is not infrequent, and a four-rayed form may occasionally be seen associated with the three-rayed embryonic desmids in the protoplasm discharged from the same spore, when germination takes place. The vegetative division often occurs by the development of a single circular bulging cell between the two semicells. The contents may divide, or an hour-glass constriction may cause the ultimate formation of two desmids.

PARIS.

Academy of Sciences, March 13.—M. Emile Bertin in the chair.—M. **Hamy**: A property of photographic emulsions and the registration of stars during total eclipses of the Sun in view of the verification of the Einstein effect. It has been found that a short exposure of a photographic plate to light of very feeble intensity, short of producing fogging, increases the sensibility of the plate, so that a plate which just shows a fifth magnitude star before this treatment shows a seventh magnitude star after the preliminary exposure, the time being the same in both cases. The bearing of this on the photography of stars round the Sun during a total eclipse is discussed.—C. **Guichard**: Networks which are harmonic to one C.L. congruence and conjugate to another C.L. congruence.—J. **Andrade**: The mechanical problems of regulating springs in chronometers.—C. **Nicolle** and E. **Conseil**: Preventive vaccination by the digestive tract in man. Experiments on voluntary subjects (Europeans) showed that the dead cultures of organisms secured immunisation in man against Mediterranean fever and dysentery. In the latter, owing to the danger of subcutaneous inoculation, the use of a digestive vaccine offers great advantages.—M. **Lecat**: Abnormal caylians and bicaylians.—K. **Popoff**: The general equation of the elliptic type.—E. **Cartan**: Generalised space and the theory of relativity.—E. **Bompiani**: The geometry of curved spaces and the energy tensor of

Einstein.—M. **Frontad**: Logoids of slipping of soil.—E. **Fichot**: The sense of rotation of cotidal lines round amphidromic points.—M. **Siegbahn**: The degree of exactitude of Bragg's law for the X-rays. Exact measurements have shown that calcite gives a small deviation from Bragg's theory, the differences although small being systematic. M. Dauvillier has recently suggested that the deviation was due to the complexity of the $K\alpha_1$ line used in the measurements; but the result is the same for the line α_2, which according to M. Dauvillier is simple.—E. **Gleditsch** and B. **Samdahl**: The atomic weight of chlorine in an ancient mineral, Balme apatite.—J. **Durand**: The thermal treatment of some cast irons. Heating to 900° C. and slow cooling increased the proportion of graphite and diminished the resistance to breaking. Tempering in oil from 900° C. and repeating to 650° C. increased the breaking load.—M. **Charriou**: The separation of ferric oxide and alumina from lime by the nitrate method.—H. **Gault** and T. **Salomon**: The α-alkyl levulinic acids.—E. **Decarrière**: The *rôle* of gaseous impurities in the catalytic oxidation of ammonia. Extremely minute proportions of hydrogen phosphide (0·2 parts per million) poison the platinum catalyst in this oxidation, but the simultaneous presence of acetylene and hydrogen sulphide, especially the latter, partially neutralises the poisonous action of the phosphorus compound.—E. **Grandmougin**: The acyl and alkyl leucoindigos.—C. **Jacob**: Eruptive rocks of the intermediate series in North Annam and in Tonkin.—P. **Corbin**: Some sections on the eastern edge of the Vercors-massif.—L. **Guillaume**: Tertiary and existing Turritella: evolution and migrations.—P. **Lesage**: The determination of the germinative faculty other than by the actual germination of the seeds. A. Němec and F. Duchon have recently described a method based on the evolution of oxygen by the action of hydrogen peroxide on the diastase of the seed as the only method available for testing the vitality of the seed other than actual germination tests. The author directs attention to a method described by him in 1911 and 1917 based on the colour imparted to dilute solutions of potash by the seeds. This gives a definite result in four hours.—J. **Bouget** and A. D. **de Virville**: The influence of the meteorology of the year 1921 on the reddening and fall of leaves.—R. **Poisson**: Histogenesis of the flight muscles in Ranatra, Nepa (*N. cimicoides* and *N. maculatus*).—G. **Bourguignon**: Modification of the chronaxy of the skeleton muscles and their nerves by the repercussion of the lesion of the neurones with which they are functionally associated.—A. **Lumière** and H. **Couturier**: Traumatic shock.—C. **Levaditi** and S. **Nicolau**: The embryonic leaflets in relation with the affinities of the vaccine virus.—E. **Fernbach** and G. **Rullier**: The action of an artificial gastric juice on tubercular pulmonary granulations of the guinea-pig.

Academy of Sciences, March 20.—M. Emile Bertin in the chair.—A. **Haller** and Mme. **Ramart-Lucas**: New distinctive characters of the three propanol-α-camphocarbonolides melting at 141°, 117°-118°, and 89°-90° C. respectively.—G. **Mittag-Leffler**: Cauchy's theorem on the integral of a function between imaginary limits.—C. **Sauvageau** and G. **Denigès**: Remarks on the efflorescences of *Rhodymenia palmata*. The presence of a xylane in these algæ. The pentosane extracted by the method of Mme. Swartz from *R. palmata* gives xylose on hydrolysis and hence is a xylane. This is the first case of the extraction of this substance from an alga.—J. **Drach**: The determination of the differential equations of the second order integrable by quadrature.—G. **Julia**: The transformation of rational substitutions into linear substitutions.—M. **Stoïlow**: The definite integral and the measurement of *ensembles*.—J. **Ubach**: Observations of the partial eclipse of the sun of October 21, 1921, made at Buenos Ayres (Argentine Republic).—F. **Michaud**: A micromanometer with sensibility capable of regulation.—A. **Guillemet**: A new objective shutter for taking aerial photographs with apparatus with long focus.—V. **Henri**: The absorption spectrum of benzine vapour and the fundamental magnitudes of the benzine molecule. The absorption spectrum of benzine vapour has been measured at pressures between 0·01 and 65 mm. The ultra-violet spectrum can be represented very exactly by a formula derived from Bohr's theory, and consists of four series of superposed bands. The results show that the molecule of benzine is a very symmetrical structure, the movements of which obey the simple laws deduced for diatomic molecules.—F. W. **Klingstedt**: The ultra-violet absorption of phenol in different solvents. The absorption spectrum of phenol in solution depends on the nature of the solvent. Comparing with the spectrum of the vapour, one type of solvent (carbon tetrachloride and ether) produces only a displacement and enlargement of the bands. The second group of solvents (methyl and ethyl alcohol, and water) change the absorption spectrum completely. The spectrum of pure liquid and solid phenol is intermediate between the two preceding types.—C. **Chéveneau**: An optical method for the determination of the reciprocal solubility of slightly miscible liquids. The method is based on the use of a hollow prism divided into several compartments. The differences of the refractive indices of the two liquids are taken directly, independently of the temperature. The case of aniline and water is given and the results compared with the gravimetric method.—G. **Guilbert**: The observation of clouds and the prediction of weather.—H. **Joly**: The existence of phenomena of horizontal displacements of large amplitude at the eastern extremity of the Iberian chain, near Montalban (province of Téruel, Spain).—H. **Coupin**: Determination of the optimum of humidity of the external medium in the Oscillaria.—A. **de Puymaly**: The reproduction of Vaucheria by amœboid zoospores.—G. **Tanret**: The chemical composition of ergot of Diss (*Ampelodesmos tenax*) and the ergot of oats. Since the closing of the Russian frontiers ergot of rye has become extremely scarce, and the possibility of obtaining ergot from other Gramineæ is of immediate interest. Of the two plants mentioned, oats only would appear to contain sufficient of the active principle to be of practical service. From one kilogram of Algerian oats 1·8 gram of crude and 0·8 gram of pure crystallised ergotinine was isolated.—C. J. **Gravier**: The relations between the Crustacean and the sponge in the sponges carrying Cirripedes.

The Education Estimates.

THE Estimates for Civil Services for the year ending March 31, 1923, have been issued, and it is expected that Class IV., which deals with Education, Science, and Art, will be discussed in Parliament almost immediately after the Easter recess. While it is now clear that the drastic cuts recommended by the Geddes Committee will not be made, the Estimates in this class still show a reduction of 7,979,154*l.* for Great Britain—Ireland being omitted from this calculation. We propose to examine three items in which economies are indicated.

First, the estimate for the Ordinary Services of the Board of Education shows a reduction of 4,898,970*l.* on the corresponding estimate for the year 1921–22, which means a cut of rather more than 10 per cent. Next, the estimate of the grant in aid of Universities and Colleges for the year 1922–23 is 300,000*l.*[1] less than the sum granted to these institutions for the year 1921–22, which means a cut of 20 per cent. And, thirdly, the estimate for Scientific and Industrial Research is reduced by 118,486*l.*—a cut of 28 per cent.

It will be observed that the cuts for higher education and research are proportionately much greater than for the Ordinary Services of the Board of Education, and it would seem that this is the considered policy of the framers of the Estimates. A closer examination of the estimate for the Ordinary Services of the Board of Education seems to confirm this opinion. Here we find that the proposed reduction in the grants to local education authorities for elementary education amounts to 1,916,307*l.* on 36,900,000*l.*, which works out as a cut of about 5 per cent.; whereas the proposed reduction of grants to local education authorities for *higher* education amounts to 954,920*l.* on 6,647,920*l.*—a cut of more than 14 per cent.

If further confirmation were needed it is to be found in the treatment of technical colleges and the grant towards students' fees. The grant to the former is to be reduced from 50,000*l.* to 40,000*l.*—a cut of 20 per cent.; while the students' fees grant, from which scholarships, studentships, and exhibitions tenable at the universities are drawn, is to be reduced from 15,000*l.* to 12,600*l.*

Obviously these facts point to the conclusion that higher education and research are bearing a greater proportion of the proposed reductions in the Education Vote than the remaining educational services. Such a discrimination requires further consideration. At the outset we may say that we have no fault to find with the rejection of the Geddes proposals regarding the salaries of school teachers. In our opinion there was ample justification for refusing to adopt proposals of that character. Rather are we concerned to point out that the proposals regarding higher education and research, if carried into effect, will, in the long run, be most injurious to education and the development of our national life. In the debate on the Consolidated Fund Bill in the House of Commons on March 28, Mr. Asquith warned the Government of "the extreme and criminal inexpediency at this time of cutting down the Education Estimates." He then proceeded to ask "Was there ever a moment in our history when it would be more suicidal to cut down the facilities which were not by any means ample enough for this great national purpose of securing the best intellectual life for the boys and girls who were most fitted to profit by it?" Far from the facilities being ample enough, we understand that at the present time 20,000 children, well qualified for higher education, are excluded from secondary schools for lack of accommodation. Yet at this particular juncture the Education Estimates, as we have indicated above, show a reduction of more than 14 per cent. in the grants to local education authorities for higher education.

While the attack upon secondary education is bad, that upon the universities is worse. A cut of 20 per cent. will have far-reaching effects. Already one university is proposing to reduce its staff, and others are preparing to follow suit. This will mean impaired efficiency and the sacrifice of future developments. A temporary and trivial economic gain will cripple the universities for many years and inflict irremediable hardships upon many deserving students. We cannot understand

[1] The proportion of the decrease for Great Britain is estimated at 247,000*l.*

how a Minister of Education can agree to a reduction of 300,000*l.* to the universities when in the debate just referred to he stated that the universities "were making contributions to learning and science exceeding in quality and amount that ever given before," and further that "it was within his knowledge that there was work proceeding in the laboratories of this country which, if the hopes of scientific men engaged upon it were realised, would repay the country over and over again for the cost." Mr. Fisher must surely know that such a reduction in the grant cannot be made without serious consequences. The sum may be small in comparison with the Education Vote as a whole, but it is most certainly large in comparison with the funds at the disposal of the universities.

The President of the National Union of Teachers in his address to the Annual Conference on April 17 was at pains to point out that money spent on scientific and technical education was productive expenditure which would become the very source of national income. And he is right. He insisted that more money was required to enlarge our control over the resources of nature. "We shall want," he says, "more money to build and equip our technical schools and colleges. We shall want more money to train our scientists and technicians, for we could not float a world trade on scientific ignorance and technical inefficiency." Again he is right. Yet the Government is proposing to reduce its grants for such purposes!

Already thoughtful men and women are realising that the hope of the future in commercial life, as well as in intellectual life, lies largely with our universities and colleges, and that any action which will prejudice their development will mean a national loss. While we hold to the same opinion we are not prepared to say that the educational system of this country is run on sound economic lines or that the system itself from a purely educational point of view is beyond criticism. Any one with inside knowledge would have no lack of material for criticism. Our point is that the proposed economies in higher education and research are specious economies which in the near future will entail losses out of all proportion to the slight temporary gain they effect. On the other hand, we believe it would not be a difficult matter to discover ways of economising which would not entail such serious consequences as those proposed. We can only hope that Parliament will show a real appreciation of the inevitable consequences of the proposed drastic cuts, and that proper means will be taken to prevent so great a calamity to higher education and research.

Studies in Symbiosis.

Tier und Pflanze in intrazellularer Symbiose. By Prof. P. Buchner. Pp. xi+462+Tafel 2. (Berlin: Gebrüder Borntraeger, 1921.) 114 mk.

THE extent and significance of symbiosis are matters of general interest. The delicate adjustments that enable yeasts to interpenetrate the tissues of insects, algae those of corals, and bacteria those of cuttlefish, resulting in mutual advantages to both partners in each association, form an evolutionary topic of no little importance. But the subject assumes practical and economic value when it is realised that the nutrition of our domestic ruminant animals is carried out not solely by their own enzymes and tissues, but is due partially to the activity of symbiotic bacteria (and probably to Protozoa also) which live within the cattle. So great has been the increase of our knowledge of these associations in the last fifteen years, that the large volume under review does not cover the whole ground, but deals only with those animals in which the invading micro-organisms take up positions within certain cells of the other partner. The no less interesting cases of symbiosis in which the invader lies in the cavity of its partner's body (as in cattle) are, with one exception, deliberately omitted.

Accustomed as we are to think of each being as working out its own salvation and that of its race, the thought of deep-seated infection of diverse animals by myriads of alien microscopic yeasts or bacteria which invade even the very germ cells and are conveyed to children's children, has in it something repulsive. Such cases, we are inclined to conclude, are exceptional. The bulk of life stands on its own ground. Symbiosis is at best a secondary phenomenon of the struggle for subsistence. It is not even a safe compromise. Co-operation may mean litigation. Mutual benefit gives place only too easily to one-sided benefit or to mutual harm. The "symbiote" becomes a parasite. Requiring such a delicately adjusted balance, symbiosis, we argue, can never have been an evolutionary factor of real and widespread significance. In opposition to the entrance of such foreign corpuscles, the body would exert all its antigens as against foreign proteids or as it does against the entrance of pathogenic spores. The struggle would lead to the survival of those forms which repelled the invaders or which tolerated their presence whilst maintaining an easy mastery.

The facts of biology, however, imperfectly known as they are and still more imperfectly apprehended in their full significance, show that the more carefully animal life is studied, the more numerous and intimate are the cases of symbiosis that investigation discloses.

Many of the blood-sucking flies, probably all, are cases of symbiosis. The whole vast order of sucking insects known as Hemiptera—the green fly, scale insect, body louse—is another. The ant and the death-watch beetle, the cockroach and the leaf-miner are examples of other orders that show the same or similar associations.

The first section of Dr. Buchner's book deals with marine plant-animals, and provides a welcome and critical summary of our knowledge of the algal associations in Protozoa, Coelenterates and Turbellaria. The second, and perhaps the most valuable, part of the work gives a full, illustrated discussion of symbiosis in insects, with especial reference to the transmission of the bacteria or yeasts to the egg and the "infection" of the embryo. This aspect of insect physiology has been neglected by English entomologists, and its significance is as yet scarcely grasped. Some indication of the importance of insect symbiosis may be gathered from the fact that Peklo has shown the symbiotic organism of green-fly to be an Azotobacter modified by residence in the tissues of the insect. The only important omission in this part of the work is that of the recent discovery of a symbiotic organism in the tsetse-fly.

Native Life in the Highlands of Assam.

The Angami Nagas, with some Notes on Neighbouring Tribes. By J. H. Hutton. Pp. xv+480. (London: Macmillan and Co., Ltd., 1921.) 40*s*. net.

Mr. Hutton's excellent monograph on the Angamis is a more than welcome accession to the series of monographs dealing with the Naga and other indigenous tribes now under the control of the Government of Assam. The volume is a very valuable contribution to the ethnological literature of the Naga Hills, and reflects great credit both upon the author, who has made full use of his opportunities, and upon the Government under the auspices of which it has been published. Ethnologists, local administrators and many others will feel grateful to the authorities for their praiseworthy encouragement of the scientific study of the natives for whose welfare they are responsible. Such detailed study is not only of value from the ethnological point of view, but has also a practical bearing upon the administration of native affairs. Accurate knowledge of the habits, customs, beliefs and culture-environment in general of primitive peoples promotes sympathetic and equitable treatment and control, and prevents those misunderstandings and unintentional acts of injustice which are due to ignorance of the native point of view, ethics, and social organisation.

The present monograph, while it deals in detail with the various phases and features of the life of the Angamis, has the merit of being brightly written and interspersed with touches of humour. It is "readable" as well as instructive.

Mr. Hutton, during several years of close contact with Naga tribes, has developed a *sympathetic* interest in them which has gone far towards winning their confidence. Much of the information which he has gleaned could have been acquired only by breaking down those barriers of reserve and distrust which are too often interposed between the representatives of

Fig. 1.—Viswema youth in ceremonial dress. From "The Angami Nagas."

government and the governed. The facts which he records have been collected mostly at first hand, being the results of his own observations. Where he depends upon the data collected by his predecessors in the field, he has endeavoured to check off their statements and, so far as possible, to verify or correct them. Many of the practices recorded by Butler, Woodthorpe, Davis, Peal, and other pioneer observers are no longer followed, and must be accepted at second hand or studied through the imperfect memory of the "oldest inhabitant." The time-honoured practice of head-hunting is rapidly becoming extinct in the administered area, and the passing of this prominent and absorbing feature in Naga culture involves the atrophy of many other cultural items and the modifica-

tion or abolition of many status-grades in Naga society. Even those striking and elaborate ornaments (Figs. 1 and 2), which were formerly guarantees of prowess on the war-path, have, to a great extent, now lost their significance, and may be worn by those who have not earned them under the rules of the old *régime*. While recognising that changes are inevitable and, no doubt, even desirable, the ethnologist views with concern the supplanting of traditional customs by "civilisation," at any rate before they have been studied and recorded in detail. Similar regrets are felt by the naturalist when some interesting zoological type becomes extinct and is no longer available for research into its life-habits. Mr. Hutton's careful record has done much towards minimising the mourning over obsolescent customs. How rapid are the culture-metamorphoses which are being effected in the Naga Hills is well reflected by the author's statement that a considerable portion of his MS. was "typed by an Angami"! Truly, there is no time to lose, and it is to be hoped that he will continue his researches without interruption.

FIG. 2.—Mozema youth in ceremonial dress. From "The Angami Nagas."

There is much to be said in praise of the Angami, whom Mr. Hutton describes as intelligent, self-reliant, honest, good-humoured, and devoted to their families. While they may be declared swashbucklers and exaggerators, they are, nevertheless, fairly truthful. Underlying these characteristics there run a vein of sadness and a considerable fear of death. Their villages, built for defensive purposes on the high ground, testify to the inter-tribal feuds, vendettas, and head-hunting raids which have hitherto retarded progress and rendered the life of every man, woman, and child somewhat precarious.

The Angamis are prominent as agriculturists, and in this industry they are ahead of the neighbouring tribes, inasmuch as they practise, for rice-growing, a very elaborate and striking system of terrace-cultivation (Fig. 3) involving complex irrigation methods. Their irrigation channels extend sometimes for miles, and water-rights are jealously guarded. This terracing of the hill-sides reminds one of that of the Bontoc-Igorots of the Philippine Islands, and it contrasts with the crude and wasteful system of *jhuming* so prevalent among Naga agriculturists, including the Angamis themselves.

These natives are skilled in several manufacturing processes, in weaving, iron-working, etc., and exhibit great artistic feeling in decorating their weapons and houses and in making their often elaborate personal ornaments. But, in spite of skill and ability to progress, severe restrictions upon culture-advancement are imposed by the complex and inexorable system of magico-religious *gennas*, or prohibitions, which play a very important part in the Angami social ritual, and exercise a retarding effect upon the prosecution of industries. The various kinds of *gennas* and their application and social significance are dealt with very fully by the author. He explains the distinction between *kenna*, which is a prohibition laid upon an individual unit of the community, and *penna*, one which involves the whole community and relates chiefly to non-working days; the latter are very numerous. Further, there is *nanü*—which embraces *any* prohibition and the whole of the active ceremonies connected with it. It is impossible in a review to deal with these social restrictions, but their dominating influence upon the whole life of the natives is very far-reaching, and their detailed study of prime importance.

The religious beliefs are vague and ill defined. There is belief in the souls of the dead and, it would seem, of the living also, and these often take the form of butterflies, as in Burma and in the Greek legend of Psyche. The reality of dreams and their value in divination are also recognised. Omens and divination to a considerable extent regulate procedure. Certain major and minor deities or spirits (*terhoma*) of greater and lesser power exist and are propitiated, and sometimes even defied, but their exact nature is but little understood. The chief of these is Kepenopfü, variously referred to as male or

female, who is the reputed creator of living things and whose abode is in the sky. Animatism prevails, and were-tigers and were-leopards are a feature in the popular beliefs. With all these matters Mr. Hutton deals interestingly and in some detail, though he wisely assumes a cautious attitude in describing the native beliefs in view of the uncertainty of the material.

Fig. 3.—Viswema village showing terraced fields. From "The Angami Nagas."

The arts, industries, amusements, and general domestic life, the laws and customs and other culture-phenomena all receive adequate attention, and a number of traditions, legends, and songs are recounted. An important chapter deals with the Angami language, which belongs to the Tibeto-Burman group. There are also several valuable appendices concerned with special points, including a series of anthropometric measurements. It is to be hoped that the Stone Age of the Naga Hills may be the object of further researches. Our knowledge of it is mainly, almost exclusively, derived from stone celts which are locally believed to be thunderbolts, and are valued as such by the natives. One assumes that other types of stone implements, which may be revealed by careful search, must have been associated with the celts. They should throw light upon the archæology of the region, a subject which as yet remains obscure.

A few words of criticism are called for. Some of Mr. Hutton's descriptions are by no means clear. For instance, on p. 68 mention is made of a "trumpet" upon which military bugle-calls are reproduced, but which is not "blown with a loose lip." If this is so, the instrument should not be described as a "trumpet," and one wonders how bugle-calls can be imitated without the "loose-lip" method of sound-production. Again, on p. 93, we learn that "millet and Job's tears . . . are . . . used for making rice beer," but these ingredients are not referred to in the description of the brewing of this staple drink, and one remains uninformed as to their function in the process. On p. 94 the reasons given for the food-*genna* to women are far from clear, and require further elucidation to show the connection of ideas. In a future edition of this excellent book it will be well if all native words and place-names are accented throughout, so as to assist the uninitiated in their correct pronunciation. This should be a general rule in all works of this nature. The illustrations are mostly good, several are very good, and they are well placed in reference to the text, but references to particular figures should appear in the letterpress. Three useful maps are added.

Mr. Hutton's enthusiasm and industry in recording the details of native life in the Naga Hills are evidenced not only in his book upon the Angamis, but also in his more recently published work on the Sema Nagas. These books are so full of information in regard to this important ethnological region that one thirsts for more, and can only hope that other Naga tribes (the Aos, Rengmas, Konyaks, etc.) may be described in a similar manner. "The Angami Nagas" may well serve as a model for further monographs. We congratulate Mr. Hutton and his readers upon a valuable and enlightening piece of work.

Henry Balfour.

The Manufacture of Explosives.

Ministry of Munitions and Department of Scientific and Industrial Research: Technical Records of Explosives Supply, 1915–1918. No. 1: *Recovery of Sulphuric and Nitric Acids from Acids used in the Manufacture of Explosives: Denitration and Absorption.* Pp. viii+56. 12s. 6d. net. No. 2: *Manufacture of Trinitrotoluene* (TNT) *and its Intermediate Products.* Pp. viii+116. 17s. 6d. net. No. 3: *Sulphuric Acid Concentration.* Pp. vi+91. 12s. net. No. 4: *The Theory and Practice of Acid Mixing.* Pp. vi+93. 12s. net. (London: H.M. Stationery Office, 1920–1921.)

The first four of the series of publications dealing with the technical records of explosives supply now to hand form a valuable addition to the literature of technical chemistry. The work of preparing the

information was begun by Mr. W. Macnab under the Ministry of Munitions, and thanks are due to the Department of Scientific and Industrial Research for arranging for his retention to complete it.

Denitration.—The first volume deals with the recovery of the nitric and sulphuric acids from the waste acid produced in the nitration of toluene and glycerine. Not only is the proportion of waste acid a large one—650 tons for 100 tons of trinitrotoluene produced—but the efficient recovery of the sulphuric acid in a condition suitable for concentration, and of the nitrogen oxy-acids as nitric acid, constitutes one of the principal economic factors of the manufacture.

The chemical reactions involved in denitration have been the subject of discussion both earlier and as a result of experience in war factories, and the position is summed up in the introduction to this volume. It may briefly be said that by considering the behaviour of nitrosylsulphuric acid when it acts on nitric acid, and when it breaks down on dilution with water, a fairly coherent explanation is afforded of what goes on during the progress of waste acids down a denitrating tower as they meet an ascending current of steam.

The treatment of the subject of the absorption of the nitrous fumes coming from the towers to form 55 per cent. nitric acid is of importance at the present time, when this problem confronts any manufacturer proposing to make nitric acid by the catalytic oxidation of ammonia. The experience recorded is that a 90 per cent. conversion of nitrogen peroxide to nitric acid can be secured with a ratio of free tower space to rate of passage of nitrogen peroxide, which is less than a tenth of that in large towers erected for the same purpose in connection with the oxidation of ammonia. The relative effectiveness of the small towers with the most advantageous conditions of concentration and velocity of gases and free space, temperature, and concentration of nitric acid, is clearly indicated, and forms a basis for modification of the present practice of installing immense absorption towers which are obviously inefficient and very costly.

Full detailed drawings are given of the plant for the processes of denitration, absorption, and storage of acids, and its applicability to the manufacture of organic nitro-bodies should make the report of interest and importance to a wider field than that of the explosive manufacturer alone.

Trinitrotoluene Manufacture.—No. 2 of this series gives the history of processes for making trinitrotoluene and for its purification, and describes plant and manufacturing methods. An account is given of the experimental work at the Research Department, Woolwich, which established the conditions necessary for nitration, the advantage of the extraction of waste acids ("detoluation") by mononitrotoluene, itself to be nitrated later, and the benefits of a cyclic system of nitration in stages in order to conserve acids. These features were embodied in the processes followed in the large factories erected for making trinitrotoluene, an important variation, however, being the elaboration at Oldbury of the counter-current method into a continuous process, which had a high capacity combined with low labour and capital cost.

In the process as carried out at the largest factory, Queen's Ferry, mononitrotoluene, made separately either by nitrating gas-works toluene or the toluene contained in Borneo petroleum, was used to detoluate waste acids which had themselves been detoluated by once-used mononitrotoluene, brought up to nearly dinitrotoluene in the last-mentioned operation, and this dinitrotoluene was then nitrated to trinitrotoluene.

The next process, that of freeing the crude trinitrotoluene from acids, underwent some elaboration, for in addition to agitation of the molten trinitrotoluene by hot water it was found efficacious to chill it by pelleting it in cold water, and to use weakly basic hydrolysable salts for the hot washing ;. a continuous system of hot washing was also developed.

But although it became possible latterly to push the process of nitration until nearly all the dinitrotoluene had been converted into trinitrotoluene, there remained about 4 per cent. of its unsymmetrical isomerides resulting from the nitration of the metanitrotoluene. While the crude trinitrotoluene, after having been washed and dried, could be used in large quantities for making the bulk of the amatol for filling shell, there were certain purposes for which a purer product was demanded, when, for example, the ammonium nitrate was not free from pyridine and thiocyanate, or when it was necessary to avoid the low melting-point eutectics formed by the isomerides. Purified trinitrotoluene was prepared at first by crystallisation from, or by washing with, organic solvents, and large factories were erected for these purposes. Later, a process was adapted from the French, safer from the point of view of fire-risk, and characterised by treating the crude trinitrotoluene with sodium sulphite solution which under suitable conditions selectively dissolves out the other isomerides, leaving the pure symmetrical trinitrotoluene and any dinitrotoluene that has escaped further nitration. As this process was one which could readily be embodied in the scheme of manufacture, it was carried out in the trinitrotoluene factory.

The plant at Queen's Ferry, which in every detail is stamped with the genius of Mr. K. B. Quinan, is described in this volume in all relevant particulars as to the main features of the manufacture. The reproductions of the working drawings, the diagrams

and flow-sheets, the detailed sketches of parts and of special devices, and the examples of methods of statistical control, constitute a body of information of a unique character. The description forms a permanent record of these matters in a connected narrative, but again its usefulness is by no means confined to the explosives manufacturer, since many of the methods used and devices for overcoming difficulties are subject-matter for numerous projects in chemical engineering.

Concentration of Sulphuric Acid.—In the third volume will be found a useful study of the thermal conditions obtaining in the Gaillard tower system. The methods used before the war in this country for concentrating the sulphuric acid of 70 per cent. strength resulting from processes of nitration were for the most part the Kessler and the cascade systems, both of which are operated with comparatively small units. Excellent results both as regards efficiency and low cost of working were obtained with the large Gaillard towers erected in the large explosives factories such as Queen's Ferry and Gretna. The feature of these towers is the conversion of the weak acid into a spray, which in falling by gravity down a tower of about 50 ft. in height, meets ascending hot gases from a producer, and so becomes concentrated to a strength of 92-95 per cent. sulphuric acid. As the fuel consumption, weight of dilute acid, and weight of concentrated acid can be measured with fair accuracy, the opportunity is taken to calculate the efficiency of the plant from a knowledge of the various thermal data available, including those of Porter for sulphuric acid and oleum. The various factors are considered in detail which will repay the study of technical students, and a satisfactory heat balance is made out in which the heat imported into the system is contrasted with that which is lost by water evaporating, by radiation, and by being carried away in the hot acids. As the last-mentioned source of loss amounts to nearly a quarter of the heat put into the system, its recovery on counter-current lines by suitable constructional modifications would appear to be worth attempting.

A short study follows of the Gilchrist concentrating plant, which worked on a process analogous to that of the Kessler plant, but with a high capacity.

It had been a disadvantage in all the varieties of concentrating plant mentioned that the gases finally discharged into the air carried with them a mist of dilute sulphuric acid in water, involving a certain loss of acid and considerable inconvenience to those working in the neighbourhood. It was also objectionable in explosives factories where many large-scale operations have to be conducted in an acid-free atmosphere. Accordingly it was determined to precipitate this mist electrically by the Cottrell electrostatic process, of which full details are given and also a description of all the electrical parts and their mode of maintenance. As about 3 per cent. of the acid fed into the concentrating plant was recovered in the Cottrell precipitating plant, it will be seen that besides the advantages mentioned, a useful addition to the yield of acid was obtained.

Acid Mixing.—In No. 4 of this series is described the working of that important section of a nitration factory in which the acids are adjusted as regards their quantity and composition. In such a factory as Queen's Ferry, where 700 tons of trinitrotoluene a week could be made, the magnitude of the problems of production, handling, and conveyance of acids may be judged from the vast quantities—about 43,000 gallons—of nitric and sulphuric acids occurring in many stages of dilution. It is essential to secure that the various acids are in balance for controlling the cycle of production and recovery in manufacture. An example for a given output of explosive is worked out, and a diagrammatic acid balance figured, which includes a set of factors by which the quantities of acid at various stages must be modified to compensate for variations in working of the units composing the acids cycle. In this way the proper quantity of mixed nitrating acids of a definite composition and the economical utilisation of spent acids are kept under strict control.

As variations in dilution and in strength of the concentrated sulphuric and nitric acid inevitably creep in, calculations must be made of the adjustments necessary to bring the contents of the large mixing vessels to the desired composition. The methods for doing this are explained, and it is of interest to note that the presentment of the necessary data in the form of graphs was abandoned in favour of a series of simple tables by means of which the necessary additions for obtaining a correct mixing could be found.

A description is given in detail of the plant for storing and mixing these acids, and this completes the account of the manufacture of trinitrotoluene contained in vol. 2.

Apart from its value as an exposition of scientific method applied to the control of acid mixing for a nitration process on the largest scale, there will be found other subject-matter, such as descriptions of the mechanical details, methods of controlling undue rise of temperature, prevention of wear of parts, and methods of distribution of acids by pipes, which will be found to have a wide interest among those concerned with the erection of plant.

It is clear that the publication of the data which

have accrued in the operation of these factories will form a permanent record of the application of scientific method to problems of chemical industry, as well as affording typical examples for the use of students as well as of manufacturers. It is to be regretted that Queen's Ferry factory, which embodies so much original work in plant construction, is now for disposal, but it is understood that while there is yet time the Disposals Board have acquiesced in an arrangement for students to study the plant. A course of this kind with Mr. Macnab's volumes as text-books should prove a very valuable means of instruction.

Popular Expositions of Relativity.

Relativity and the Universe: A Popular Introduction into Einstein's Theory of Space and Time. By Dr. Harry Schmidt. Authorised Translation by Dr. Karl Wichmann. Pp. xiii + 136. (London: Methuen and Co., Ltd., 1921.) 5*s.* net.

The Ideas of Einstein's Theory: A Theory of Relativity in Simple Language. By Prof. J. H. Thirring. Translated by R. A. B. Russell. Pp. xv + 167. (London: Methuen and Co., Ltd., 1921.) 5*s.* net.

An Introduction to the Theory of Relativity. By L. Bolton. Pp. xi + 177. (London: Methuen and Co., Ltd., 1921.) 5*s.* net.

Relativity and Gravitation. Edited by J. Malcolm Bird. Pp. xiv + 245. (London: Methuen and Co., Ltd., 1921.) 8*s.* 6*d.* net.

The Rudiments of Relativity: Lectures delivered under the Auspices of the University College, Johannesburg, Scientific Society. By Prof. J. P. Dalton. Pp. vi + 105. (London: Wheldon and Wesley, Ltd., 1921.) 5*s.* net.

Die Einsteinsche Gravitationstheorie: Versuch einer allgemein verstandlichen Darstellung der Theorie. Von Prof. G. Mie. Pp. iv + 67. (Leipzig: S. Hirzel, 1921.) 7 mk.

HERE are six accounts of the Relativity theory designed for the general reader. The first four hail from Messrs. Methuen, who had the enterprise to secure an English translation of Einstein's own popular exposition, and have also recently published a translation of Weyl's "Space, Time and Matter." The fifth is published in Johannesburg by the Council of Education, Witwatersrand. The last comes from the pen of an eminent German professor of physics.

In surveying such a collection it is appropriate to quote from the last named. "We cannot penetrate into the thought-world of a symphony by reading a description of it, be it by the most distinguished musical critic. The symphony must be heard. The more we analyse it note by note, and the more deeply we understand the relations of the notes, the more do we come into the real meaning of the work."

That is the feeling which emerges after going one after another through many attempts to describe this new theory without asking the reader that he should first equip himself for the act of appreciation by an intimate study of the technique and terminology of geometry, of the significance of Newton's theory of gravitation and his system of mechanics both as an explanation of known phenomena and as forming the whole basis of the further development of physical science. But even granting these prime requisites, the reader is desired, on the strength of the reading of a few simple pages, to readjust the whole of his outlook on the world to an degree even greater than that required for one brought up in a classical school of art to comprehend the strivings of the moderns to find a new mode of expression for the thoughts of a new age.

This much is certain, that there is no short-cut to an understanding of Einstein's achievement. What is the most that we can expect from these many attempts to supply the public with some answer to their inquiries for light on this latest achievement of the imagination and intellect in co-operation? We may legitimately ask for some presentation of the historical setting. But even here we are faced with a great difficulty in providing an account which is free on the one hand from technical difficulties and on the other from misleading vagueness. For the precise statement of the actual achievements of Newton is in itself a matter requiring so much detail that the majority of our university students would not show up well in an examination on this subject. They are content with a parrot-like learning of the conventional language in which the laws of motion are expressed, and a false facility in doing problems without any reference to their physical significance. Meanwhile the Newtonian conceptions of space and time are absorbed as if they were strictly obvious, whereas the mere fact of the existence of Newton's definitions of absolute space and time shows that after all his investigations he found himself bound to postulate something which his reason and conscience could not justify. Newton's absolute space, like Euclid's axiom of parallels, were last confessions of remaining mysteries rather than preliminary statements of the obvious.

Yet it is not possible to appreciate the bearing of the relativity theory without appreciating first the point at which the classical mechanics is unsatisfactory. For it is perhaps the greatest merit of Einstein's work that it gives us something which is more satisfactory

just at this point. Einstein has met the greatest of all objections both to Newtonian mechanics and to Euclidean geometry. He has satisfied the logicians, and it so appears that, beginning with this sole end in view, he has found the explanation of the outstanding discrepancy with observation.

After the historic setting the most important element in an exposition of this theory is an analysis of the nature of measurement and of exact observation. The new element in the general theory of relativity is directly concerned with this. Einstein insists on the fact that the use of co-ordinates to distinguish between events is a piece of mathematical machinery; that the physical facts are there, and are the same, whatever descriptive method we may employ. On the other hand, measurement is simply a particular part of physical observation. On this point much more exact thinking is needed. The expositions of relativity, on the other hand, almost without exception encourage more than usually loose thinking. The strictest logical analysis cannot be avoided.

But after all the test of a popular exposition is whether it is really illuminating to the amateur reader. The reviewer is not entitled to pass hasty judgment. Nor is he entitled to compare these books on the score of their strict accuracy in detail. For the success of the author's attempt is relative to the previous knowledge and habit of thought of the reader.

One or two words of reference to the par icular features of these publications may, however, be made. Dr. Schmidt's account is colloquial and entertaining, and shows that the author feels the story of physical science to be part of the wonder book of the universe. Dr. Thirring is more severe and academic; but at the same time is lucid and free from exaggerations and misleading illustrations. Mr. Bolton's essay is interesting as the expansion of the 3000-word essay which won the prize offered by the *Scientific American*. Mr. Bolton remarks in his preface that the general drift of the theory was a greater obstacle to an understanding of the subject than the details of the advanced mathematical work, and he has written the book with a lively recollection of his own troubles. The fourth of Messrs. Methuen's publications is the most interesting. It is a collection of the best portions of the essays sent in for the *Scientific American* prize. This book will give hours of interesting reading from a multitude of points of view.

Dr. Dalton's Lectures in Johannesburg have been reproduced attractively and are very readable, while Prof. Gustav Mie gives us the point of view of one who has himself contributed a good deal to the discussion of fundamental physical theories.

The Induction Motor.

The Induction Motor and other Alternating Current Motors. By B. A. Behrend. Second edition, revised and enlarged. Pp. xxiii+272. (New York and London: McGraw-Hill Book Company, Inc., 1921.) 24*s*. net.

A FULL discussion is given in this book of the practical theory of the induction motor and of several of the main types of alternating current motors. The author also gives a historical account of the invention of the induction motor and of the development of its theory. He attributes the invention to Nikola Tesla in 1888. In England it is generally attributed to Ferraris, who certainly made an induction motor, the rotating part of which was a solid copper cylinder, in the autumn of 1885. In this connection also, Baily has some claim to be called the inventor, as he showed a disc revolving in a rotating magnetic field to the Physical Society of London in June 1879. Tesla and the Westinghouse Co., however, were the first to make a motor similar to those used to-day. They had great difficulties to contend with, as the standard frequency of alternating current supply in America in 1888 was 135.

In 1895 the author first developed his theory of the induction motor. He showed that in an ideal motor the locus of the extremity of a vector representing a phase current is a circle, and that from this circle the engineer can foretell the working of the machine. This circle diagram has proved of the greatest value to the designer and is in world-wide use, although it is known that in consequence of certain assumptions made in the course of the proof it is only an approximation. An immense amount of ingenuity has been expended in trying to make it more accurate, but we are very doubtful of the value of these corrected diagrams. Very often the authors unwittingly introduce new assumptions—for instance, that all the vectors lie in one plane—which may introduce appreciable errors into their results.

There are two parts in an induction motor, the stator or fixed part containing the windings carrying the polyphase currents which produce the rotating magnetic field, and the rotor, which is rotated by this field and from which mechanical power is taken from a pulley on its shaft. The induced alternating currents in the rotor are quite distinct, and have a different frequency from the alternating currents in the stator. The mutual inductance coefficients between the stator and rotor windings are not constants, and the inductances of the windings are only approximately constant. The problem is therefore difficult, and great credit is due to the author for discovering that the speed,

torque and efficiency at all loads can be found very simply by constructing a certain circle and drawing various lines.

Theory shows that the torque developed when switching one of these motors into circuit is greatly increased by increasing the resistance of the rotating circuits. Many inventions have been devised, so that the resistance of the rotor circuits automatically diminishes as the speed increases, thus securing high initial torque with economic working. It is interesting to learn that in the rotors of the two-phase motors used in the U.S. battleship *New Mexico* there are two windings. The outer is made of a high-resistance alloy and the inner has low resistance. The outer winding produces the initial torque, but the inner produces the greater torque at normal speed.

The author defines the leakage factor of a motor as $L_1L_2/M^2 - 1$, where L_1, L_2 are the inductances of a stator and rotor winding respectively and M is the mutual inductance between them. We much prefer Behn-Eschenburg's definition, namely, $1 - M^2/L_1L_2$. The latter is always a fraction lying in value between 0 and 1. The former varies between 0 and infinity. We also think it better to talk about motors being "in cascade" rather than "in concatenation." We regard this book as an important contribution to the practical theory of alternating current machinery.

A. Russell.

Our Bookshelf.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol. xxiii.: *Lead and Zinc Ores in the Pre-Carboniferous Rocks of West Shropshire and North Wales.* Part 1, West Shropshire. By B. Smith. Part 2, North Wales. By H. Dewey and B. Smith. Pp. iv+95. (Southampton: Ordnance Survey Office; London: E. Stanford, Ltd., 1922.) 3s. net.

Reports on the lead and zinc ores of Scotland, of Cornwall, Devon and Somerset, of the Lake District, and of the carboniferous rocks of North Wales have already appeared, and the three remaining volumes of the series, dealing with British lead and zinc ores in the remainder of the country, are promised shortly. It is of the utmost importance in the interests of economic geology that this work should be done now, before it is too late; but unfortunately it is becoming only too clear that the interest is a purely academic one, and that the industry of lead and zinc mining in Britain is in a moribund condition. It is obviously impossible that our relatively small deposits, some of which have probably been worked for 2000 years, can compete in the world's markets against the vast masses of mineral, the development of which is of quite recent date, which are to be found in the United States, Australasia, Burma, etc., and it must be regretfully admitted that it is impossible to bolster up an industry that has to contend with such crushing disadvantages, both natural and artificial. For reasons that are well known to all students of mineral deposits, our veins of lead ore were richer and more easily worked at the outcrops than they are to-day; we are far indeed from the days of Pliny, according to whom lead was found in Britain near the surface of the ground in such abundance that it was found necessary to limit strictly the output.

The volume before us describes the occurrences of lead and zinc in two districts, which have probably been thus grouped together on account of their marked geological similarity, the ores in both occupying fault fissures in the older rocks of Cambrian, Ordovician and Silurian age. The individual mines are described accurately and minutely, and the description is in many cases supplemented by sections taken from the actual mine plans. It is only to be regretted that more attention has not been paid to the introductory chapters dealing with the districts as a whole, particularly as regards the statistical portion. No summary of district statistics is given for North Wales, and that for Shropshire is indicated only by means of a small graph, which shows the general features of its rise and fall, but from which it is impossible to obtain exact figures.

H. L.

Elementary Chemical Microscopy. By Prof. E. M. Chamot. Second edition, partly rewritten and enlarged. Pp. xvi+479. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 25s. net.

The first edition of this work was reviewed at some length in Nature in 1915 (vol. 96, p. 84) shortly after its appearance. The subject of chemical microscopy, however, received a great impetus during the war, many new applications revealing themselves in the special war industries, which resulted in a more extensive use of the microscope in applied chemistry than at any time during the last quarter of a century. Hence, a new edition of this book was found necessary in America, and it is somewhat disappointing to find that practically no new methods or processes, and but little new apparatus, are described. The lack of photomicrographs of typical microscope fields of characteristic crystals produced in the tests described is still very obvious, but the author on the one hand promises a second book to make good this deficiency, and on the other states that this present book is primarily intended as a text-book (especially for the students of Cornell University), and not as a book of reference, and that the method of instruction in the Cornell course is intentionally one which leads to the best results when the student is encouraged to discover for himself (under guidance) the characteristic morphology of the materials studied.

The same more or less antiquated crystallography is retained, in which such terms as "optical elasticity," "hemihedral," and "tetartohedral" constantly occur, and the confusion between trigonal and hexagonal crystals is so complete that the former term is not even mentioned.

This second edition is, however, an improvement, for several obscure portions of the first edition have been

rewritten, and some of the inadequate practical details have been amplified. The chapter on the ultramicroscope stands out, as before, as one of the best in the book, and the later apparatus of Zsigmondy is here described. Moreover, the book is clearly printed in good-sized type, and the illustrations, although only the reproductions of line drawings, are unusually good for this class of figure. A. E. H. T.

(1) *Photo-Engraving Primer: Concise Instructions for Apprentice Engravers or for those seeking simple yet practical knowledge of Line and Half-Tone Engraving.* By S. H. Horgan. Pp. xvi+100. (London: P. Lund, Humphries and Co., Ltd., 1921.) 5*s.* net.

(2) *Byepaths of Colour Photography.* By O. Reg. Edited and with an Introduction by William Gamble. Pp. xii+116+xiii-xx. (London: P. Lund, Humphries and Co., Ltd., 1921.) 5*s.* net.

Both these volumes are by "practical men," and they are characterised to the full, if we may say so, by the advantages and the disadvantages that might be expected to result from this fact. Each has a critical and, to a certain extent, supplementary introduction by Mr. W. Gamble, so that the reader may feel fully assured that he is in safe hands. (1) Mr. Horgan goes clearly and concisely over the subject as he has practised it, and as he is a man of great and prolonged experience, his instructions cannot fail to be of value to the student, whether or not he has arrived at the stage of workman. But it is not a treatise on the subject. The author leaves theory quite on one side, though here and there he justifies his directions by a shrewd statement of the trouble likely to follow variations of them. Perhaps the chief matter to notice is that Mr. Horgan uses collodion, while in this country gelatine plates have largely replaced it.

(2) Mr. Reg clearly describes his own system in which he uses a one-exposure camera, with one reflector and one compensator, and plates specially sensitised. He gives full details as to the making of the camera, formulæ for sensitising the plates, and instructions for the general procedure. Rather more than half the volume is devoted to throwing what he calls "sidelights" on certain notions of previous inventors. Here he is not always lucid, and his excursions into theory are not always fortunate. But he has been a diligent searcher with regard to the methods of other workers in this field, and gives many useful dates and references to patents, with illustrations of apparatus. He calls his volume "byepaths," and in this sense it is both useful and interesting. C. J.

Forestry for Woodmen. By C. O. Hanson. Second edition. Pp. 238+13 plates. (Oxford: At the Clarendon Press, 1921.) 6*s.* 6*d.* net.

During the ten years that have elapsed since the first edition of this book was published, much progress in the art of forestry has been made in this country. The necessity of having within our shores an ample store of growing timber to meet the possible emergency of war, is now admitted by statesmen. The Forestry Commission established in 1919 has been busily engaged in acquiring land for new plantations and in re-afforesting the extensive areas which were denuded of timber during the war. Municipalities are awakening to the useful work of covering their water-catchment areas with trees, as evidenced by the new scheme of the Glasgow Corporation, which, if carried out, will create around Loch Katrine a magnificent forest, such as that owned by Liverpool at Vyrnwy in Wales.

The interest in forestry is increasing, and there is a demand for elementary instruction on the subject. This has been met by the publication of the second edition of this useful manual. It is well adapted for the purpose, being cheap in price, handy in form, and simple in language. Scarcely any change has been made in the original text, but two chapters have been added. One deals with the Forestry Act of 1919 and the Forestry Commission, and gives a summary of recent developments. The other new chapter treats briefly the afforestation of waste land, and gives a sketch of the survey necessary before any planting scheme can be decided upon. The book is brought up to date by the intercalation of a new paragraph here and there, and it may be recommended to landowners, as well as to agricultural students and forestry apprentices, as a satisfactory guide to elementary forestry. The index is, however, incomplete, and should be enlarged to double its present size in a new edition.

Problemi di Filosofia Botanica. By Antonino Borzi. Pp. 344. (Roma: G. Bardi, 1920.) 60 lire.

The introduction of this posthumous work contains a short historical sketch of vegetable biology, as foreshadowed by the elder Agardh, Delpino (to whose memory the book is dedicated), Haeckel, and others. The scope of the book itself is best indicated by the chapter headings: I. General conceptions and limits of vegetable ecology; II. Ecological principle of vegetable organisation; III. Ecological principles of vegetable associations; IV. Ecology of dissemination; V. Aerophylactic function in the vegetable kingdom; VI. Hydrophylactic function in the vegetable kingdom; VII. Form and evolution of the earliest vegetable life. VIII. Ecological conception of the evolution of the vegetable kingdom.

The author, a specialist on Cyanophyceæ, sums up very ably in chap. vii. his observations on the evolution of that group, and describes their extraordinary adaptability to varying ecological conditions. Continuous vegetative reproduction means a progressive development, from which no return to an earlier stage ever occurs; but development of the sexual function arrests such indefinite evolution and lays the foundation of constant characters. "Mutation" occurs before the development of sex. The polyphyletic origin exemplified in Cyanophyceæ is also manifested in the scheme of the entire vegetable kingdom.

The view generally held, that subaqueous life represents the primitive condition of terrestrial vegetation is regarded as unproved. Hydrophytes and aerophytes are probably two distinct stocks, the former representing primitive vegetation, the latter originating as Vascular Cryptogams at the period of land-emergence. That Bryophytes may possibly be survivals of a transitional stage between Hydrophytes and Aerophytes is not sufficiently clear. These views are set forth in detail.

40 Blätter der Karte des Deutschen Reiches 1 : 100,000 *ausgewählt für Unterrichtszwecke.* Erläuterungen bearbeitet von Dr. W. Behrmann. Veröffenlicht von der Gesellschaft für Erdkunde zu Berlin. Zweite Auflage. Size 17 in. × 15 in. Handbook, Pp. 62. (Berlin: R. Eisenschmidt, 1921.) Germany, 60 marks; England, 180 marks.

The portfolio of forty maps under notice consists of reprints of German surveys on the scale of 1 to 100,000. The first edition, published some nine years ago, was essentially the same except for three sheets, Metz, Gebweiler, and Oltingen, which have been omitted since the regions they cover are now outside German territory. Three other sheets have been substituted. The collection has been made for educational purposes, and with this end in view illustrates as many types of land forms and geographical features as possible within the limits of the country. The sheets, which are in black and white, are finely printed and leave no ground for criticism as regards reproduction. Surface features of relief are shown by hachures only. This method, excellent as it may be for a general impression, gives no absolute information and precision of detail. It has also the disadvantage of making the map so dark on the steeper slopes that other symbols, and particularly the names, are almost illegible. In fact, if these sheets have any great fault, it is one common to most German maps, namely, the attempt to show more than the scale will allow. In spite of this, however, the collection should prove extremely useful, and might well be imitated for the British Isles by the Ordnance Survey. A pamphlet giving a description of the sheets accompanies the portfolio.

Physical Map of England and Wales, 1 : 1,000,000. Size 34½ in. × 26 in. (Southampton: Ordnance Survey Office, 1922.) 2*s.* (Not less than 20 copies for educational purposes, 1*s.* each.)

The Ordnance Survey has produced a beautifully printed map which leaves little to be desired in the way of cartographical skill and excellence in reproduction. Surface relief is shown by layer colouring in green and brown. The contours are at 200, 400, 800, 1200, and 2000 feet. Rivers, lakes, and water names are in blue; other names are in black. No submarine relief is shown. The addition of this would improve the map for educational purposes. Some criticism may be offered with regard to the names. These are comparatively few in number; this is certainly an advantage, but a few more names of physical features might have been inserted. The fine black type used for these names does not obscure the map, and we miss such names as Charnwood Forest, Solway Plain, Fenland, Forest Ridges, or Aire Gap. The system on which the town names, printed in heavy black, have been selected is not very apparent. Such towns as Oldham, Sunderland, Gainsboro', Yarmouth, and Goole, to mention only a few large places, are omitted while many relatively unimportant names are to be found. The nearest towns to Manchester to be found on the map are Buxton, Liverpool, and Northwich, while in other less populated parts of the country the names are more crowded. No administrative names and no communications are marked. The low price is noteworthy.

Contribution à l'Étude de la Flore du Katangar. Par E. de Wildeman (Comité Spécial du Katanga). Pp. viii + cxliv + 264. (Bruxelles: D. Reynaert, 1921.) n.p.

The large district of Katanga forms the south-eastern corner of that part of Africa which is now under Belgian rule. It is governed by the Comité Special du Katanga, under the auspices of which this account of the vegetation of the country has been prepared and published. Four districts are recognised in considering the flora, namely, the Kasai, the middle Katanga or Upper Congo, the district of the great lakes, or the Tanganyika region, which forms the eastern limit, and the Upper Katanga district. A sketch is given of the botanical geography of the two last-mentioned districts; and Dr. de Wildeman dissents from Scott Elliot's view that the Tanganyika basin forms botanically merely a part of the great western Congo-Niger area, but regards it as an area with very special characters.

The Upper Katanga is described in greater detail, and some features of its vegetation are illustrated by a number of photographic reproductions. Dr. de Wildeman insists on the importance of the conservation of the forests; the number of useful species at present known is not great, but forestry investigations will probably reveal others. A large portion of the volume is occupied with a systematic enumeration of the flowering plants already known from the area; these number about 1900, but probably represent less than half the actual flora. A map of the whole district, indicating its relation to surrounding districts, would have been a useful addition.

Technique des Pétroles. By R. Courau. Pp. 406 + 19 Plates. (Paris: Octave Doin, 1921.) Price 16 francs.

Practically every phase of petroleum technology is covered by this volume, and as a general text-book it will be of considerable utility. Much of the subject matter is treated somewhat summarily, particularly in the geological section; in fact this suffers from undue brevity when contrasted with the engineering and chemical aspects of the science.

The arrangement of the text is systematic, and it is primarily divided into two books, the first dealing with the geology and economic development of petroleum, and the second with its chemical and physical properties, methods of refining, storage, and transport. Unlike many books of this description, there is no overcrowding with tables of constants, statistics, etc., and space is therefore available for a consideration of certain technical operations which either receive scanty treatment or are omitted altogether from similar publications elsewhere. We should have preferred, however, the inclusion of the figures in the text rather than in their less convenient form of plates at the end of the book, while the omission of a detailed index is also rather unfortunate. Apart from this and the fact that the present rate of exchange makes the book an extremely cheap purchase in this country, it is well worth reading, if only to obtain the French view of current oilfield development and refinery technique.

H. B. Milner.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Discoveries in Tropical Medicine.

IT is a matter for regret that the obituary notice of a well-known medical man should be used to put forward a statement of his share in the progress of knowledge which is misleading. It is necessary to correct such a statement when it is conspicuous and likely to be accepted as truthful. In a brief biography of the late Sir Patrick Manson in the *Times* of April 10, it is stated that "modern tropical medicine" was born when he suggested that the *Filaria sanguinis hominis*—discovered some years previously by Dr. Timothy Lewis in persons afflicted with elephantiasis —"is taken from one person to another by mosquitoes." On the ground that this was the first suggestion as to the carriage of disease-germs by mosquitoes, *and was well founded*, the chief merit in the later discoveries of the part played by those insects in the transmission of malaria and of yellow fever is attributed by the *Times* to Sir Patrick Manson.

This, however, is a misapprehension, the propagation of which must do injustice and falsify history. The fact is that Manson's "suggestion" that the Filaria of elephantiasis is actually carried by mosquitoes from the blood of one person to that of another remains to this day a "suggestion." It has not been established as a fact.

Another important misconception enunciated in the same article is that no suggestion as to the mode of entry of the malaria parasite into the blood of human beings was made until Manson, fourteen years after their discovery by Laveran, "suggested" mosquitoes as the carriers. The fact, on the contrary, is that Laveran himself had stated this to be a possible and not improbable mode of transmission, and that the notion was long ago prevalent in India. The man who actually "discovered" the fact of the carriage of malaria germs by a mosquito and the particular species (*Anopheles maculipennis*) so concerned, as well as important facts as to the multiplication of the malarial parasite in the gnat's body, is Sir Ronald Ross.

Finally, the *Times* states that General Sir David Bruce is a disciple of Sir Patrick Manson. This is a peculiarly unfortunate assertion, for it makes it necessary to state the fact, well known to their colleagues, that Bruce, so far from being a disciple of Manson, disapproved of his suggestions and of his methods. The man of genius who discovered and finally abolished Malta fever, who by laborious years of work in Africa gave us solid and absolutely new knowledge of the Tsetze fly and Trypanosome diseases, nagana and sleeping-sickness—not to mention his war work in conjunction with pupils and colleagues on tetanus and on trench fever—was not in any way, directly or indirectly, influenced by or associated with Sir Patrick Manson. The attempt to associate the discoveries of Bruce with the Manson legend is a mere assertion regardless of fact and of the pain which it must cause to the friends of both.

E. RAY LANKESTER.

April 17.

Atmospheric Refraction.

IN NATURE of August 11, 1921, p. 745, appeared my letter in which I criticised a result stated by Mr. Mallock in NATURE of June 9, p. 456; and also a further brief letter by Mr. Mallock. Further letters have appeared by Dr. Ball (January 5, p. 8) and Instr. Commander Baker, R.N. (January 5, p. 8, and January 26, p. 105). In his second letter Mr. Mallock says that "the pressure gradient near the ground, and the density and refractive-index gradients also, decrease linearly at such a rate that if the linear relation continues to hold, the pressure and density would be zero and the refractive index unity at height H." This statement is incorrect as regards the density and refractive-index gradients, except in the special case when the temperature gradient is zero.

The relation between density and refractive index, $\mu-1=K\rho$, where K is constant ($=222 \cdot 16$ for sodium line D), shows that $d\mu/dh=Kd\rho/dh$, and so it is only necessary to consider the density gradient. Using suffixes $_1$, $_0$ to indicate values at sea level and at the upper limit of the atmosphere, the height H of the homogeneous atmosphere is given by $\int_1^0 \rho g dh = \rho_1 g_1 H = p_1$. Hence $p_1/H=\rho_1 g_1$, and by the ordinary mechanical law of equilibrium this is equal to $-(dp/dh)_1$, proving Mr. Mallock's statement as regards the pressure gradient.

Now if the absolute temperature near the level considered (sea level) is given by $t=t_1(1-\alpha h)$, then $p=Ct\rho=Ct_1(1-\alpha h)\rho$, which differentiated logarithmically gives for $h=0$, $(d\rho/dh)_1=-\rho_1(1-H\alpha)/H$. This result agrees with Mr. Mallock's only when $\alpha=0$, that is, when the temperature gradient is zero.

The curvature $1/\sigma$ of a ray inclined at an angle ϕ to the vertical is derived from $\mu r \sin\phi=\text{constant}$, $d\psi=d\phi+\sin\phi ds/r$, whereby $1/\sigma=d\psi/ds=-K\sin\phi d\rho/dh=(1-H\alpha)\sin\phi \,.\, K\rho/H=(1-H\alpha)\sin\phi(\mu-1)/H$, a result applicable to any point of the ray if H is understood to mean the height of the homogeneous atmosphere, of density ρ at the point, above the point. Here again agreement with Mr. Mallock is obtained if $\alpha=0$ and $\phi=90°$, *i.e.* for a horizontal ray.

Introducing the temperature gradient $\beta=t_1\alpha$, we see that $H\alpha=C\beta/g_1=29 \cdot 28\beta g_{45}/g$. Also $(\mu-1)/H$ varies as Bg/t^2, B being the barometer reduced reading. Hence

$$\frac{1}{\sigma}=3 \cdot 665\times10^{-5}\frac{B}{760}\cdot\frac{g}{g_{45}}(1+at)^{-2}\left(1-29 \cdot 28\beta'\frac{g_{45}}{g}\right)\sin\phi,$$

where $a=1/273$, β' is fall of temperature t per metre, and σ is in kilometres. No mention has been made of humidity for the reason that its action is chiefly to modify the temperature gradient, which has been allowed for.

If we multiply $1/\sigma$ by the earth's mean radius, 6371 km., we obtain $2k$, according to the Indian definition of coefficient of refraction k; or k, according to the continental definition. The result is to change the numerical factor in $1/\sigma$ into $0 \cdot 2335$. This agrees well with Jordan's formula quoted by Dr. Ball, which I had not previously seen and which, I believe, has never been used by surveyors. For $B=760$ mm. and latitude 45° we can write

$$\sigma=27285\,(1+at)^2(1-29 \cdot 28\beta')^{-1}\operatorname{cosec}\phi \text{ kilometres.}$$

The following table gives values of the radius of curvature σ in miles of a horizontal ray at level $B=760$ mm., and the coefficient of refraction as defined in India.

Gradient. Degrees Centigrade per metre.	σ in miles.		k (Indian).	
	$t=0°$	$t=10°$	$t=0°$	$t=10°$
0·000 (isothermal) .	16,980	18,220	0·117	0·109
0·006 (average) .	20,600	22,100	0·096	0·090
0·010 (adiabatic) .	24,000	25,760	0·082	0·077
0·03414	infinite		zero	

Mr. Mallock's value, 14,900 geographical miles = 17,150 miles, agrees nearly with the isothermal value for $t=0°$. (In my former letter I had not recognised that Mr. Mallock's result was in nautical miles.) The result is too small as a usual value, because he takes the temperature gradient as zero and the surface temperature to be freezing point. Dr. Ball's explanation is incorrect as pointed out by Commander Baker (January 26); and further in that he states in his second paragraph that the difficulty is not to be got over by any consideration of temperature gradient.

Commander Baker, in his letter (January 5) has arrived at a similar result, for a horizontal ray, as I have. The temperature gradient, however, of 1° C. per 200 feet, which he says will give my results, is in error; it should be per 600 feet.

In the second paragraph of this letter, Commander Baker says that neither Mr. Mallock nor I give an adequate presentation of the facts, in that the assumption is made that the ray is circular. I do not think that this deduction can be made rightly from my former letter of August 11. I may say at once that I entirely agree that the ray is not in general circular, especially when the ray is close to the earth or sea surface. However, in cases met with in land surveys (excepting rays which continue very close to the ground) one may *compute the refraction practically* by the use of a coefficient of refraction which represents the curvature at height $(2h_a+h_b)/3$, as stated in my letter. The use of different coefficients of refraction for different heights essentially involves the idea of a ray of varying curvature except in the case of a truly horizontal ray.

Now work on the diurnal change of refraction on inclined rays shows up the importance of the varying conditions of temperature gradient in the layers near the earth. I have not yet been able to reduce the case of rays, which lie mostly or largely in these lower layers, to a formula, though I think there is fair hope of doing so in some cases. Extreme cases, in which there is obvious and varying mirage, will not be amenable to treatment: but I think a ray, 20 feet above the surface, probably will. But I gather that Commander Baker is chiefly interested in rays over the sea, at a height of 30 feet or less. In the Survey of India such cases naturally do not arise, and I have not had any observations of this kind to consider. However, in my Professional Paper No. 14 (Survey of India) I have given some deductions as regards dip of the horizon (*vide* pp. 96-100), arriving at the formula

Dip in seconds from point at height $h=$

$$56{\cdot}33(h'-15{\cdot}13\Delta t')^{\frac{1}{2}}$$

where $\Delta t'=\mathrm{F}\Delta t$, $h'=h(1-0{\cdot}2204\mathrm{F})/0{\cdot}7796$, $\mathrm{F}=519{\cdot}4/t$, $t+\Delta t$ and t being the absolute temperatures at levels of observer and sea respectively. This formula is based on $\cos(\text{dip})=(1+h/r)^{-1}\mu_0/\mu$ which involves only the terminal values of μ.

I have tabulated the corresponding dip in Tab. LIII. *loc. cit.* for various values of h' and $\Delta t'$, and I should be very interested to hear from Commander Baker or others to what extent my formula represents the facts of observations. J. de Graaff Hunter.

Survey of India, Dehra Dun, U.P., India, March 2.

I agree with Dr. Hunter that my letter of January 5 contained a numerical error when I stated that a temperature gradient of 1° C. per 200 feet would give a ray curvature corresponding to the refraction coefficient given in his letter of August 11, 1921.

Dr. Hunter also takes me to task for my comment that both he and Mr. Mallock assume the refracted ray to be circular. I think I have a certain amount of justification for this, as in his letter of August 11 he speaks of the curvature of the ray "tacitly assumed to be circular," although later it is true that he states that the coefficient of refraction has different values at different heights.

It was rather in connection with the formulæ upon which the nautical tables for the dip of the sea horizon are based that I take exception to any assumption that adequate results can be obtained unless variations of curvature are considered.

As stated in my letter of January 5, it is impossible to draw a circle which touches the surface of the sea and also becomes horizontal at a height of say 30 feet above the sea, and unless consideration is given to a form of ray path that can satisfy these conditions it is impossible to get a zero value for the dip.

Dr. Hunter quotes from his Professional Paper No. 14 (Survey of India) a formula which he has set out there from which the dip is to be evaluated, and asks to what extent this formula represents the facts of observations. I have, unfortunately, no data of measurement of the dip made in connection with the temperatures of the sea level and at the bridge, but on theoretical grounds I cannot admit that this formula is correct. It will be seen that the dip becomes zero whenever $h'=15{\cdot}13\Delta t'$, which is equivalent to saying that, if the temperature rises uniformly 1° F. per 15 feet, the dip is zero at all heights. Consider now what will happen to a ray of light which starts off from the surface of the sea tangentially. In an atmosphere of uniform refractive index that ray would proceed in a straight line and ultimately depart from the earth entirely. With a refractive index that diminishes with height the ray will be bent towards the earth, and if the rate of diminution is great enough that ray will at some point become horizontal and the dip will be zero. Let us say that this point is at a height of 30 feet above the sea. Dr. Hunter's formula requires that the temperature should be 2° more at 30 feet than at sea level, and if the rise of temperature is uniform in this 30 feet his formula also requires that the dip should be zero, and therefore the ray horizontal, at all heights below 30 feet. This is obviously a fallacy, for if the ray was always horizontal it would never reach the height of 30 feet at all.

The fact is that in an atmosphere where the layers of uniform refractive index are spheres concentric with the earth, the dip can only be zero, if at all, at one height. Below that height the dip will be positive with a maximum value at some lower level; above that height no ray tangential to the earth's surface can be seen at all, and the depression or elevation of the sea horizon requires an entirely different explanation.

The equation upon which Dr. Hunter's formula is based brings out this point quite clearly. This equation is

$$\text{Cos (dip)}=\mu_0 r/\mu(r+h).$$

In an atmosphere in which $\mu(r+h)$ is, at some height, less than $\mu_0 r$ the dip becomes imaginary, for its cosine is greater than unity. The dip could only be zero for all heights for an atmosphere in which $\mu(r+h)$ is constant, and in such case a ray once horizontal would remain horizontal for a complete circuit of the earth. Thos. Y. Baker.

Memory.

MEMORY is the power to learn, to grow mentally in response to functional activity, to profit from experience, and so to become intelligent. It has its counterpart in the power to develop physically in response to use. Its evolution occurred especially among the higher animals, and was accompanied by a general retrogression of instinct. Nevertheless, at least four new instincts were evolved, each of which incites to learning, and without which little or no intelligence could develop, no matter how great the capacity to learn.

(1) The parental instinct incites to the protection and training of offspring. It wanes when offspring are fit to fend for themselves.

(2) The instinct of sport impels the individual to develop both body and mind in exactly the right directions. Thus the kid climbs and butts, and the kitten stalks and pounces. This instinct wanes as the individual reaches maturity and ability to battle for existence. It lingers longest in human beings who remain capable of some mental development even to old age. But the character of human sport gradually changes from those contests of strength and endurance which developed the boy to those which merely maintain physical development, or else are pure contests of skill and wit. Thus the mature man ceases to wrestle, and amuses himself instead with golf, bowls, cards, and the like.

(3) The instinct of imitation incites the individual to learn (from the examples furnished by his companions) how to act and what to think. It often works in combination with play (for much play is mimicry), and wanes in the individual even more swiftly and in a greater degree than the latter. While it persists in strength the individual is termed "plastic." It is best developed in man, who learns through imitation not only such habitual actions as walking and speaking a language, but also the habits of thought, the general outlooks on life, the ambitions, and the emotional convictions as to what is true and right that distinguish the community (or section of it) in which he is reared, savage or civilised, Christian or Mohammedan, Catholic or Protestant, lowly or exalted, and so on. In this way he fits himself for life in that particular environment. Thus, mainly, is fashioned what is termed his "character," his general mental disposition. As the twig is bent, so the tree grows. Hence the importance of good homes, companions, and schools. As this instinct wanes the character sets. The same kind of things are no longer learned, at any rate to the same extent and with equal facility. Compare language as learned by a child and by an adult. It follows that the traits created by imitation tend to be very stable, for they are not afterwards displaced by others of the same kind. The boy becomes the father of the man.

(4) The instinct of curiosity impels the individual to seek for, and learn from, evidence. Unlike imitation, it persists with relatively little diminution even to old age. To it (and to labour) the individual owes the main part of his mental development after childhood, his intelligence, his reason. It creates, not sentimental, but intellectual convictions. Since it persists during life, the ideas acquired through it tend to be unstable—apt to be displaced by others which seem founded on superior evidence.

(5) Apart from instinct, man, especially civilised man, has invented labour, to which he is impelled by the intelligence created through his memory, and from which he learns to become yet more intelligent, efficient, and laborious. Thus, as indicated by Prof. Goodrich, in the mental, as in the physical, world each stage of development furnishes the basis for the next until full development is achieved. Labour commonly lacks the pleasure and interest which accompany the instinctive activities. Thus, while men never delegate the latter (*e.g.* eating, sporting, and love-making) to others, they often delegate the labours to which they are prompted by intelligence. Like play and imitation, but unlike curiosity, labour tends to create habitual "physical" dexterities—which are really mental, for the (subconscious) mind co-ordinates the muscles. On the other hand, the intellectual traits created by labour resemble those created by curiosity.

We are concerned especially with the products of imitation and curiosity. All the rest of the "make-up" of man's mind is relatively simple and obvious. His instincts, few in number and definite in character, are identical in kind for all men. At most this man or this race may have this instinct or that (*e.g.* the sexual or parental) more or less developed than this or that other. Again, all men except idiots are eminently educable. They differ in capacities for learning, but yet more in the way in which the capacity is used. Apart from play and labour, the results of which are glaringly obvious, men learn only through imitation and curiosity; and accordingly as they acquire more through the one than through the other, their characters are shaped and the fates of nations decided. Here must the parent and the pedagogue learn or be impotent. Here must the man of science labour, or charlatans and fanatics will for ever dominate the body politic.

The mental traits created by imitation and curiosity differ sharply. Not only are convictions derived from example very stable, but they are tinged with emotion, and even passion. The reverse is the case with those derived from evidence. Compare moral and religious convictions, which belong to the former category, with business and scientific beliefs, which belong to the latter. A religious and ethical system may conflict daily with common sense (*i.e.* evidence), and yet persist for a hundred generations. But the knowledge and ideas acquired through curiosity change in every man with every year. When men believed on grounds of faith (*i.e.* through imitation) that the world was flat they burned dissentients; to-day, when they believe on grounds of fact (*i.e.* on grounds of evidence) that it is round, they are contemptuously indifferent. Every missionary knows the ease with which the children of non-Christians may be trained to his beliefs and ideals, and the difficulty and danger of trying to convert adults. A child who is taught that honesty is right will for ever hold that opinion; an adult taught that honesty is the best policy may easily change. If there be such things as absolute right and wrong, the human mind is incapable of knowing them; for the conscience, chameleon-like, is a product of imitation. Thus at different times and places everything, from promiscuous sexual intercourse to rigid abstention from all intercourse, has been held holy, or permissible, or damnable, and conscience has pricked men correspondingly.

The traits created by imitativeness—habitual emotions and ways of acting—resemble closely the instinctive emotions and actions. Thus men and horses walk, men and ants are social, men and bees defend their communities; but while the men have learned, the others have not. The love of a human mother for her baby is instinctive, that for her mature offspring is habitual; yet the one passes insensibly into the other. Did we not know that the children of Mohammedans could be trained to other beliefs and ideals we might think the fanaticism of the adults instinctive. So closely do habitual actions and

emotions resemble their instinctive prototypes that they are often thus described—as when a woman shrinks from untruth or a caterpillar, or when a boy dodges a blow. Habits are, in fact, pseudo-instincts; they have the same function; they are substitutes. Unlike real instincts, they are not infallibly useful, but, on the whole, they are superior, for they fit the individual to his particular environment, and, since they may change in future generations otherwise than by slow processes of natural selection, may be improved more rapidly.

On the other hand, the traits created by curiosity bear no resemblance to instincts. They are intellectual, not emotional. In the little child the two instincts work hand in hand, but in the adult they are often opposed; for the traits derived from imitation (faith, right belief, and morality, as we term them in ourselves; bias, prejudice, fanaticism, and superstition, as we call them in others) may prevent the development of those traits which curiosity should bestow—as is best seen among savages, creatures of custom and emotion, who, following from age to age in the ancestral footsteps, add little to their command over nature. Among modern civilised peoples the ecclesiastical mind is especially a product of imitation, the scientific mind of curiosity. Consider how unlike they are, and how different all societies trained mainly through imitation (*e.g.* medieval Christians and modern Mohammedans) are from those trained through curiosity (*e.g.* ancient Greeks and the more "enlightened moderns").

Walaeus and the Circulation of the Blood.

It has been my good fortune to come across two epistles written by Johannes Walaeus (1604–1649), professor of medicine in the University of Leyden in the year 1640. The two epistles occur at the end of Bartholini's "Anatomy," published by Nich. Culpeper, Gent., and Abdiah Cole, Doctor of Physick: printed (in English) by Peter Cole; London, 1665.

Walaeus was greatly interested in the discovery of the circulation of the blood by Harvey, and in order to confirm it performed a large number of experiments on dogs, cats, rabbits, and monkeys. Having arrived at the conclusion already reached by Harvey, that the blood does not move itself, but is driven, he asks the questions "How is it driven?" and "What is the mechanism?" The answer is given in these two epistles written by Johannes Walaeus to his friend Bartholini, the professor of anatomy at the University of Copenhagen, and is as follows:—

"And that the Blood is driven by the *Vena Cava* into *the right Earlet of the Heart*, I have manifestly seen in the dissection of live Creatures: for in all motions of the Heart, the first beginning of Motion is so or no, because the Cava was knit to the Earlet [*i.e.* Auricle] and the Heart, we cut the Heart and the Earlet quite off in living Dogs, at the *Vena Cava*, and we observed, that even then the *Vena Cava* did a very little pulse, and at every time did send forth a little Blood. And therefore the *Vena Cava* hath certain fleshy fibres, for the most part about the Heart, which elsewhere you shall not find in *Vena Cava*. Now the motion of the *Vena Cava* is most evident near the Heart."

Writing in 1913 Sir James Mackenzie says: "Until very recent times no definite remains of the sinus venosus had been found. Keith and Clark have described a small node of tissue—the sino-auricular node—at the mouth of the superior vena cava. This tissue consists of fine, delicate, pale fibres faintly striated." In the same year Dr. (now Sir Thomas) Lewis tells us that "the wave of contraction starts in a small and newly discovered mass of tissue the sino-auricular node, which lies embedded in the upper and anterior end of the sulcus terminalis."

On the subject of auricular fibrillation Walaeus is also very interesting for he tells us that "the Impulse into both Earlets and into both Ventricles happens at one and the same moment of time; save in Creatures ready to die, in which we have observed that both Earlets, and both Ventricles do not pulse at one and the same time. But when the Blood is thus driven into the Ventricles of the Heart, the Heart hath no motion evident to the Eye, but putting our Finger upon the Heart we perceive something to enter into the Heart, and that the Heart becomes fuller, which also Harvey hath observed. Yea, we have observed that the Earlet hath pulsed seventy, sometimes an hundred pulses before any motion of the Heart followed." Somewhat similar observations had, however, already been made by Harvey ("De motu cordis et sanguinis," 1628, Chapter IV.).

Transcription of Russian Names.

Some 35 years ago I made in the columns of Nature the proposal to adopt for the transcription of Russian names a few letters from the Bohemian alphabet. My letter was submitted to the authority of the editor of the Journal of the Chemical Society (for I was at that time Abstractor of that Journal for Russian literature), but he did not agree with my proposal, though later he accepted it for the Journal.

I beg to repeat my old proposal; for a great part of Russian scientific life is concentrated in Prague, and the Bohemian mode of transcription has, moreover, been accepted by philologists and by many geographers. Bohemian is now the State-tongue of an independent State. It is necessary to introduce only the following few letters: č = tch, ď = dj, ě = ye, ch = kh, ň = nj, š = sh, ť = tj, and ž = zh (joli); á = long a, and if you add the Bohemian ř which has two pronounciations: rž and rš, you can pronounce also all Bohemian names.

The following comparison between the old and new mode of spelling shows that the latter has also the advantage of a great economy in printing:

Tchitcherine (12)	= Čičerin (7)
Zhemtchuzhnyj (13)	= Žemčužnyj (9)
Mendeleeff	= Mendělějev
Konj (4)	= Koň (3)
Tatjana (8)	= Taťána (6)
Pushkine (8)	= Puškin (6)
Djadja (6)	= Ďáďa (4)
Metchnikoff (11)	= Měčnikov (8).

Evolutionary Faith and Modern Doubts.[1]

By W. Bateson, F.R.S.

I VISIT Canada for the first time in delightful circumstances. After a period of dangerous isolation, intercourse between the centres of scientific development is once more beginning, and I am grateful to the American Association for this splendid opportunity of renewing friendship with my western colleagues in genetics, and of coming into even a temporary partnership in the great enterprise which they have carried through with such extraordinary success.

In all that relates to the theme which I am about to consider we have been passing through a period of amazing activity and fruitful research. Coming here after a week in close communion with the wonders of Columbia University, I may seem behind the times in asking you to devote an hour to the old topic of evolution. But though that subject is no longer in the forefront of debate, I believe it is never very far from the threshold of our minds, and it is with pleasure that I find it appearing in conspicuous places in several parts of the programme of this meeting.

Standing before the American Association, it is not unfit that I should begin with a personal reminiscence. In 1883 I first came to the United States to study the development of Balanoglossus at the Johns Hopkins summer laboratory, then at Hampton, Virginia. This creature had lately been found there in an easily accessible place. With a magnanimity that on looking back I realise was superb, Prof. W. K. Brooks had given me permission to investigate it, thereby handing over to a young stranger one of the prizes which in this age of more highly developed patriotism, most teachers would keep for themselves and their own students. At that time one morphological laboratory was in purpose and aim very much like another. Morphology was studied because it was the material believed to be most favourable for the elucidation of the problems of evolution, and we all thought that in embryology the quintessence of morphological truth was most palpably presented. Therefore every aspiring zoologist was an embryologist, and the one topic of professional conversation was evolution. It had been so in our Cambridge school, and it was so at Hampton.

I wonder if there is now a single place where the academic problems of morphology which we discussed with such avidity can now arouse a moment's concern. There were of course men who saw a little further, notably Brooks himself. He was at that time writing a book on heredity, and, to me at least, the notion on which he used to expatiate, that there was a special physiology of heredity capable of independent study, came as a new idea. But no organised attack on that problem was begun, nor had any one an inkling of how to set about it. So we went on talking about evolution. That is barely 40 years ago; to-day we feel silence to be the safer course.

Systematists still discuss the limits of specific distinction in a spirit which I fear is often rather scholastic than progressive, but in the other centres of biological research a score of concrete and immediate problems have replaced evolution.

Discussions of evolution came to an end primarily because it was obvious that no progress was being made. Morphology having been explored in its minutest corners, we turned elsewhere. Variation and heredity, the two components of the evolutionary path, were next tried. The geneticist is the successor of the morphologist. We became geneticists in the conviction that there at least must evolutionary wisdom be found. We got on fast. So soon as a critical study of variation was undertaken, evidence came in as to the way in which varieties do actually arise in descent. The unacceptable doctrine of the secular transformation of masses by the accumulation of impalpable changes became not only unlikely but gratuitous. An examination in the field of the interrelations of pairs of well-characterised but closely allied "species" next proved, almost wherever such an inquiry could be instituted, that neither could both have been gradually evolved by natural selection from a common intermediate progenitor, nor either from the other by such a process. Scarcely ever where such pairs co-exist in nature, or occupy conterminous areas do we find an intermediate normal population as the theory demands. The ignorance of common facts bearing on this part of the inquiry which prevailed among evolutionists was, as one looks back, astonishing and inexplicable. It had been decreed that when varieties of a species co-exist in nature, they must be connected by all intergradations, and it was an article of faith of almost equal validity that the intermediate form must be statistically the majority, and the extremes comparatively rare. The plant breeder might declare that he had varieties of Primula or some other plant, lately constituted, uniform in every varietal character and breeding strictly true in those respects, or the entomologist might state that a polymorphic species of a beetle or of a moth fell obviously into definite types, but the evolutionary philosopher knew better. To him such statements merely showed that the reporter was a bad observer, and not improbably a destroyer of inconvenient material. Systematists had sound information, but no one consulted them on such matters or cared to hear what they might have to say. The evolutionist of the 'eighties was perfectly certain that species were a figment of the systematist's mind, not worthy of enlightened attention.

Then came the Mendelian clue. We saw the varieties arising. Segregation maintained their identity. The discontinuity of variation was recognised in abundance. Plenty of the Mendelian combinations would in nature pass the scrutiny of even an exacting systematist and be given "specific rank." In the light of such facts the origin of species was no doubt a similar phenomenon. All was clear ahead. But soon, though knowledge advanced at a great rate, and though whole ranges of phenomena which had seemed capricious and disorderly fell rapidly into a co-ordinated system, less and less was heard about evolution in genetical circles, and now the topic is dropped. When students of other

[1] Address delivered before the American Association for the Advancement of Science at Toronto on December 28, 1921.

sciences ask us what is now currently believed about the origin of species we have no clear answer to give. Faith has given place to agnosticism for reasons which on such an occasion as this we may profitably consider.

Where precisely has the difficulty arisen? Though the reasons for our reticence are many and present themselves in various forms, they are in essence one; that as we have come to know more of living things and their properties, we have become more and more impressed with the inapplicability of the evidence to these questions of origin. There is no apparatus which can be brought to bear on them which promises any immediate solution.

In the period I am thinking of, it was in the characteristics and behaviour of animals and plants in their more familiar phases, namely, the zygotic phases, that attention centred. Genetical research has revealed the world of gametes from which the zygotes—the products of fertilisation—are constructed. What has been there witnessed is of such extraordinary novelty and so entirely unexpected that in the presence of the new discoveries we would fain desist from speculation for while. We see long courses of analysis to be travelled through and for some time to come that will be a sufficient occupation. The evolutionary systems of the eighteenth and nineteenth centuries were attempts to elucidate the order seen prevailing in this world of zygotes and to explain it in simpler terms of cause and effect: we now perceive that that order rests on and is determined by another equally significant and equally in need of "explanation." But if we for the present drop evolutionary speculation it is in no spirit of despair. What has been learned about the gametes and their natural history constitutes progress upon which we shall never have to go back. The analysis has gone deeper than the most sanguine could have hoped.

We have turned still another bend in the track and behind the gametes we see the chromosomes, for the doubts—which I trust may be pardoned in one who had never seen the marvels of cytology, save as through a glass darkly—cannot, as regards the main thesis of the Drosophila workers, be any longer maintained. The arguments of Morgan and his colleagues, and especially the demonstrations of Bridges, must allay all scepticism as to the direct association of particular chromosomes with particular features of the zygote. The transferable characters borne by the gametes have been successfully referred to the visible details of nuclear configuration.

The traces of order in variation and heredity which so lately seemed paradoxical curiosities have led step by step to this beautiful discovery. I come at this Christmas season to lay my respectful homage before the stars that have arisen in the west. What wonder if we hold our breath? When we knew nothing of all this the words came freely. How easy it all used to look! What glorious assumptions went without rebuke. Regardless of the obvious consideration that "modification by descent" must be a chemical process, and that of the principles governing that chemistry, science had neither hint, nor surmise, nor even an empirical observation of its working, professed men of science offered positive opinions very confidently on these nebulous topics which would now scarcely pass muster in a newspaper or a sermon. It is a wholesome sign of return to sense that these debates have been suspended.

Biological science has returned to its rightful place, investigation of the structure and properties of the concrete and visible world. We cannot see how the differentiation into species came about. Variation of many kinds, often considerable, we daily witness, but no origin of species. Distinguishing what is known from what may be believed, we have absolute certainty that new forms of life, new orders and new species have arisen on the earth. That is proved by the palæontological record. In a spirit of paradox even this has been questioned. It has been asked how do you *know* for example that there were no mammals in palæozoic times? May there not have been mammals somewhere on the earth though no vestige of them has come down to us? We may feel confident there were no mammals then, but are we sure? In very ancient rocks most of the great orders of animals are represented. The absence of the others might by no great stress of imagination be ascribed to accidental circumstances.

Happily, however, there is one example of which we can be sure. There were no Angiosperms—that is to say, "higher plants" with protected seeds—in the carboniferous epoch. Of that age we have abundant remains of a world-wide and rich flora. The Angiosperms are cosmopolitan. By their means of dispersal they must immediately have become so. Their remains are very readily preserved. If they had been in existence on the earth in carboniferous times they must have been present with the carboniferous plants, and must have been preserved with them. Hence we may be sure that they did appear on the earth since those times. We are not certain, using certain in the strict sense, that the Angiosperms are the lineal descendants of the carboniferous plants, but it is very much easier to believe that they are than that they are not.

Where is the difficulty? If the Angiosperms came from the carboniferous flora why may we not believe the old comfortable theory in the old way? Well so we may, if by belief we mean faith, the substance, the foundation of things hoped for, the evidence of things not seen. In dim outline evolution is evident enough. From the facts it is a conclusion which inevitably follows. But that particular and essential bit of the theory of evolution which is concerned with the origin and nature of *species* remains utterly mysterious. We no longer feel as we used to do, that the process of variation, now contemporaneously occurring, is the beginning of a work which needs merely the element of time for its completion; for even time cannot complete that which has not yet begun. The conclusion in which we were brought up, that species are a product of a summation of variations, ignored the chief attribute of species, that the product of their crosses is frequently sterile in greater or less degree. Huxley very early in the debate pointed out this grave defect in the evidence, but before breeding researches had been made on a large scale no one felt the objection to be serious. Extended work might be trusted to supply the deficiency. It has not done so, and the significance of the negative evidence can no longer be denied.

When Darwin discussed the problem of inter-specific sterility in the "Origin of Species" this aspect of the

matter seems to have escaped him.[1] He is at great pains to prove that inter-specific crosses are *not always* sterile, and he shows that crosses between forms which pass for distinct species may produce hybrids which range from complete fertility to complete sterility. The fertile hybrids he claims in support of his argument. If species arose from a common origin, clearly they should not always give sterile hybrids. So Darwin is concerned to prove that such hybrids are by no means always sterile, which to us is a commonplace of every-day experience. If species have a common origin, where did they pick up the ingredients which produce this sexual incompatibility? Almost certainly it is a variation in which something has been added. We have come to see that variations can very commonly—I do not say always—be distinguished as positive and negative. The validity of this distinction has been doubted, especially by the Drosophila workers. Nevertheless in application to a very large range of characters, I am satisfied that the distinction holds, and that in analysis it is a useful aid. Now we have no difficulty in finding evidence of variation by loss. Examples abound, but variations by addition are rarities, even if there are any which must be so accounted. The variations to which inter-specific sterility is due are obviously variations in which something is apparently added to the stock of ingredients. It is one of the common experiences of the breeder that when a hybrid is partially sterile, and from it any fertile offspring can be obtained, the sterility, once lost, disappears. This has been the history of many, perhaps most of our cultivated plants of hybrid origin.

The production of an indubitably sterile hybrid from completely fertile parents which have arisen under critical observation from a single common origin is the event for which we wait. Until this event is witnessed, our knowledge of evolution is incomplete in a vital respect. From time to time a record of such an observation is published, but none has yet survived criticism. Meanwhile, though our faith in evolution stands unshaken, we have no acceptable account of the origin of "species."

Curiously enough, it is at the same point that the validity of the claim of natural selection as the main directing force was most questionable. The survival of the fittest was a plausible account of evolution in broad outline, but failed in application to specific difference. The Darwinian philosophy convinced us that every species must "make good" in nature if it is to survive, but no one could tell how the differences—often very sharply fixed—which we recognise as specific, do in fact enable the species to make good. The claims of natural selection as the chief factor in the determination of species have consequently been discredited.

I pass to another part of the problem, where again, though extraordinary progress in knowledge has been made, a new and formidable difficulty has been encountered. Of variations we know a great deal more than we did. Almost all that we have seen are variations in which we recognize that elements have been lost. In addressing the British Association in 1914 I dwelt on evidence of this class. The developments of the last seven years, which are memorable as having provided in regard to one animal, the fly Drosophila, the most comprehensive mass of genetic observation yet collected, serve rather to emphasise than to weaken the considerations to which I then referred. Even in Drosophila, where hundreds of genetically distinct factors have been identified, very few new dominants, that is to say positive additions, have been seen, and I am assured that none of them are of a class which could be expected to be viable under natural conditions.

If we try to trace back the origin of our domesticated animals and plants, we can scarcely ever point to a single wild species as the probable progenitor. Almost every naturalist who has dealt with these questions in recent years has had recourse to theories of multiple origin, because our modern races have positive characteristics which we cannot find in any existing species, and which combinations of the existing species seem unable to provide. To produce our domesticated races it seems that ingredients must have been added. To invoke the hypothetical existence of lost species provides a poor escape from this difficulty, and we are left with the conviction that some part of the chain of reasoning is missing. The weight of this objection will be most felt by those who have most experience in practical breeding. I cannot, for instance, imagine a round seed being formed on a wrinkled variety of pea except by crossing. Such seeds, which look round, sometimes appear, but this is a superficial appearance, and either these seeds are seen to have the starch of wrinkled seeds or can be proved to be the produce of stray pollen. Nor can I imagine a fern-leaved Primula producing a palm-leaf, or a star-shaped flower producing the old type of *sinensis* flower. And so on through long series of forms which we have watched for twenty years.

Analysis has revealed hosts of transferable characters. Their combinations suffice to supply in abundance series of types which might pass for new species, and certainly would be so classed if they were met with in nature. Yet, critically tested, we find that they are not distinct species, and we have no reason to suppose that any accumulations of characters of the same order would culminate in the production of distinct species. Specific difference therefore must be regarded as probably attaching to the base upon which these transferables are implanted, of which we know absolutely nothing at all. Nothing that we have witnessed in the contemporary world can colourably be interpreted as providing the sort of evidence required.

Twenty years ago, de Vries made what looked like a promising attempt to supply this so far as Oenothera was concerned. In the light of modern experiments, especially those of Renner, the interest attaching to the polymorphism of Oenothera has greatly developed, but in application to that phenomenon the theory of mutation falls. We see novel forms appearing, but they are no new species of Oenothera, nor are the parents which produce them pure or homozygous forms. Renner's identification of the several complexes allocated to the male and female sides of the several types is a wonderful and significant piece of analysis introducing us to new genetical conceptions. The Oenotheras illustrate in

[1] He refers to it, however, in "Animals and Plants," chap. xix., and adduces the sterility which he observed in several of his illegitimately raised plants of Lythrum, arguing that this sterility, arising from the crossing of co-derivatives, is comparable with that produced by the intercrossing of true species. The details are given in "Forms of Flowers," chap. v. Without more evidence the genetical nature of these plants cannot be conjectured with much confidence, but it is highly improbable that the parallel really holds.

the most striking fashion how crude and inadequate are the suppositions which we entertained before the world of gametes was revealed. The appearance of the plant tells us little or nothing of these things. In Mendelism, we learnt to appreciate the implication of the fact that the organism is a double structure, containing ingredients derived from the mother and from the father respectively. We have now to admit the further conception that between the male and female sides of the same plant these ingredients may be quite differently apportioned, and that the genetical composition of each may be so distinct that the systematist might without extravagance recognise them as distinct specifically. If then our plant may by appropriate treatment be made to give off two distinct forms, why is not that phenomenon a true instance of Darwin's origin of species? In Darwin's time it must have been acclaimed as supplying all and more than he ever hoped to see. We know that that is not the true interpretation for that which comes out is no new creation.

Only those who are keeping up with these new developments can appreciate fully their vast significance or anticipate the next step. That is the province of the geneticist. Nevertheless, I am convinced that biology would gain greatly by some co-operation among workers in the several branches. I had expected that genetics would provide at once common ground for the systematist and the laboratory worker. This hope has been disappointed. Each still keeps apart. Systematic literature grows precisely as if the genetical discoveries had never been made, and the geneticists more and more withdraw each into his special "claim"—a most lamentable result. Both are to blame. If we cannot persuade the systematists to come to us, at least we can go to them. They too have built up a vast edifice of knowledge which they are willing to share with us, and which we greatly need. They too have never lost that longing for the truth about evolution which to men of my date is the salt of biology, the impulse which made us biologists. It is from them that the raw materials for our researches are to be drawn, which alone can give catholicity and breadth to our studies. We and the systematists have to devise a common language.

Both we and the systematists have everything to gain by a closer alliance. Of course we must specialise, but I suggest to educationists that, in biology at least, specialisation begins too early. In England certainly, harm is done by a system of examinations discouraging to that taste for field natural history and collecting, spontaneous in so many young people. How it may be on this side, I cannot say, but with us attainments of that kind are seldom rewarded, and are too often despised as trivial in comparison with the stereotyped biology which can be learned from text-books. Nevertheless, given the aptitude, a very wide acquaintance with nature and the diversity of living things may be acquired before the age at which more intensive study must be begun, and is the best preparation for research in any of the branches of biology.

The separation between the laboratory men and the systematists already imperils the work, I might almost say the sanity, of both. The systematists will feel the ground fall from beneath their feet, when they learn and realise what genetics has accomplished, and we, close students of specially chosen examples, may find our eyes dazzled and blinded when we look up from our work-tables to contemplate the brilliant vision of the natural world in its boundless complexity.

I have put before you very frankly the considerations which have made us agnostic as to the actual mode and processes of evolution. When such confessions are made the enemies of science see their chance. If we cannot declare here and now how species arose, they will obligingly offer us the solutions with which obscurantism is satisfied. Let us then proclaim in precise and unmistakable language that our faith in evolution is unshaken. Every available line of argument converges on this inevitable conclusion. The obscurantist has nothing to suggest which is worth a moment's attention. The difficulties which weigh upon the professional biologist need not trouble the layman. Our doubts are not as to the reality or truth of evolution, but as to the origin of *species*, a technical, almost domestic, problem. Any day that mystery may be solved. The discoveries of the last twenty-five years enable us for the first time to discuss these questions intelligently and on a basis of fact. That synthesis will follow on an analysis, we do not and cannot doubt.

Alternating-Current Mineral Separation.[1]

By PROF. S. J. TRUSCOTT, Imperial College (Royal School of Mines), South Kensington.

INVESTIGATION of the possible use of alternating current in magnetic separation, either in the direction of obtaining a rotary field by polyphase currents, or otherwise, has hitherto not resulted in any useful discovery. Recently, however, Mr. W. M. Mordey, past president of the Institution of Electrical Engineers, by arranging poles energised by two-phase currents to follow one another across the stream, has succeeded in driving iron minerals and iron compounds in that direction. This effect is not one of ordinary magnetic attraction and repulsion, but apparently a display of "hysteretic repulsion," a repulsion consequent upon the magnetism residual after each alternation, and made continuous by the moving field contributed by polyphase current.

A laminated alternating-current magnet behaves towards magnetite or iron-filings much like a direct-current magnet, in that tufts of these materials form at the poles, from which lines of force radiate. On the other hand, towards such a feebly magnetic mineral as hæmatite no attraction appears to be exercised but a decided repulsion is witnessed, for example, when a dish containing powdered hæmatite is laid upon an upturned pole. This repulsion is continuous when the dish spans a number of poles and these are energised by polyphase current. Similar repulsion of magnetite occurs at a lower excitation or when the dish is lifted sensibly off the poles.

[1] W. M. Mordey, Transactions South African Institute of Electrical Engineers, December 1921.

From the foregoing it seems probable that ordinary magnetic attraction and hysteretic repulsion determine between them the behaviour of particles in the field of an alternating-current magnet. Of these two factors the former is fairly understood; it remains to indicate one or two points concerning the latter. Hysteretic repulsion is low and attraction relatively high when the frequency of alternation is low, and *vice versa*; Mr. Mordey found that, with an increase of frequency from 25 to 75 periods, the speed at which the material was repelled increased approximately as the square of the increase in frequency. At higher frequencies, however, repulsion appears to be again inactive; Mr. Mordey, for example, found that both at 150 periods and at 350, repulsion was not manifest but attraction, even hæmatite remaining over the poles. He used relatively low inductions, 560 to 2000, these being more proper to alternating current than the higher inductions associated with direct current in ordinary magnetic separation.

The continuous repulsion of the ferriferous particles across the stream is forceful and unhesitating, whether these particles be dry or borne in water; it is assisted by an upward repulsion which frees them from entanglement with associated gangue, and gives them power to climb an inclination or even the sides of the container. At the same time, however, these particles, and particularly those of magnetite, tend to be held strongly in the plane of their movement, so that unless the field be properly adjusted transverse walls or banks form such as hinder the escape of gangue.

To make use of this discovery Mr. Mordey has in mind a shallow inclined launder down which the material would flow in the condition of an ore-pulp. With poles running the length of this launder the ferriferous particles would be driven to one side, to be collected separately at the bottom, the gangue particles keeping a straight path.

It is interesting that only iron minerals have so far been found capable of making the transverse movement, such moderately magnetic minerals as ilmenite and wolframite not moving; it is also of interest that, though magnetite moves more strongly, hæmatite can hardly be said to be outclassed; further, a small contamination with iron oxide causes other minerals to move, wolframite and cassiterite, for instance.

Obviously, therefore, though magnetic susceptibility is doubtless involved it does not enter unfettered; as already stated, it is associated with hysteretic repulsion. That the repulsion may be due to eddy currents set up in the particles appears to be excluded by the fact that the conductivity of hæmatite is not high enough to permit any pronounced development of such currents; moreover, particles of metallic aluminium, the conductivity of which is very high, are not repelled.

It is to be hoped that this process of magnetic separation may so develop that deposits, such as that at Dunderland, Norway, which contain much hæmatite in addition to magnetite, and others consisting largely of granular hæmatite, may be successfully treated. In view of the many deposits coming within these descriptions, and of the fact that the present means of magnetic separation, good as they are for dry work, fail entirely to separate feebly-magnetic minerals from a water-borne pulp, any endeavours to realise this hope will be viewed by all with the greatest sympathy and interest. The ordinary magnetic concentration of magnetite is not an expensive treatment, but the treatment outlined by Mr. Mordey, being simplicity itself, would cost still less.

Obituary.

Prof. J. C. Branner.

Prof. John Casper Branner, president emeritus of Stanford University, California, died at Palo Alto, California, on March 1, in his seventy-second year. He was a geologist of stimulating activity, and was attracted to Brazil as a young man in 1874 through his master at Cornell, C. F. Hartt. In 1875 he succeeded Hartt as director of the Imperial Geological Commission in Brazil, and, on the establishment of the republic, continued his observations in that country on various expeditions from time to time. In 1885 he was appointed professor of geology in Indiana University, and in 1892 to the similar post in the newly founded Stanford University. He won a considerable position as an economic botanist, and his geological papers cover a wide and practical field. His "Outlines of the Geology of Brazil," the second edition of which was published in the Bulletin of the Geological Society of America as recently as 1920, has been noticed in Nature, vol. 106, p. 58. This very useful summary includes a geological map of the whole country on the scale of 1 : 5,000,000.

Many European geologists will remember Branner at the International Geological Congress in Zürich in 1894, and all who met him must have been won by his strong personality and his equally strong and manly presence. It is characteristic of his outlook that in his most recent treatise he hopes that his work may be of service to the Brazilian people, "to whom I am strongly attached, and in whose welfare I am deeply interested."

We owe some of the facts and dates in the foregoing notice to an appreciative article by Dr. David Starr Jordan in *Science* for March 31, and to an obituary notice in the *American Journal of Science* for April.

Dr. Andrew McWilliam, C.B.E.

The death of Dr. Andrew McWilliam, which occurred on April 5, came as a shock to a large circle of friends and former pupils, and deprives the steel world of a metallurgist of great knowledge and wide experience. A native of Galloway, Dr. McWilliam was educated at Allan Glen's School, Glasgow, and at the Royal School of Mines, of which he became an Associate. On leaving South Kensington, he entered the Sheffield Technical School, afterwards incorporated with the University of Sheffield, but later he left to take up in succession several outside posts. Returning to Sheffield, he was first appointed lecturer, and then assistant professor,

in metallurgy, and began that long association with Dr. Arnold in the development of the University as a centre of metallurgical education and research. Besides the work of training chemists and managers for the steel industry of the city, the two collaborators published numerous papers containing important contributions to metallurgy, and were always ready to assist local manufacturers by advice, by conducting special investigations, and when necessary by defending their patent rights against attacks.

In 1911 Dr. McWilliam left for India to become government inspector of steels in that country, and held that responsible position for six years. He then entered the Tata Iron and Steel works and for a year did excellent service in the technical reorganisation of the steel departments. On his return to Sheffield he took up a consulting practice, for which he was peculiarly qualified from his intimate knowledge of the manufacture and properties of steels of high quality. As an active member of technical societies, he could always be counted on to illuminate a discussion by drawing on his stores of experience and by his shrewd criticism and ready wit. His good literary style is seen to advantage in the well-known work "Modern Foundry Practice," which he wrote in collaboration with Dr. Longmuir. Of fine presence and genial manner, he was a popular figure in the city of his adoption, and enjoyed the esteem and affection of his friends and colleagues, among whom were so many who owed to him a part of their metallurgical training.

We learn from the *British Medical Journal* of the death on March 26 of Dr. W. Ainslie Hollis at the great age of eighty-two years. Dr. Hollis was educated at Cambridge and St. Bartholomew's Hospital, receiving his M.D. in 1871. He was elected a Fellow of the Royal College of Physicians of London in 1876. Most of his life was spent at Brighton, where he set up in private practice; but his activities led him more to literary and scientific pursuits, during the course of which he made a fine collection of British macrolepidoptera. He was president of the Brighton and Sussex Medico-Chirurgical Society and of the Brighton Natural History and Philosophical Society, and in 1913 he served as president on the occasion of the Brighton meeting of the British Medical Association. Dr. Hollis was the author of numerous contributions to medical journals on disseminated fibrosis of the kidney, the duration of life in infective endocarditis, and other topics.

The death is announced, in his sixty-third year, of Dr. Henry Edgerton Chapin, who was professor of biology in Ohio University from 1891 to 1900. He then removed to New York to teach biology and physiography in the high schools there. He was the author of many scientific monographs, and collaborated in writing Chapin and Rettger's "Elementary Zoology and Guide."

We much regret to announce the death on April 21, in his seventy-third year, of Sir Alfred Bray Kempe, F.R.S., treasurer of the Royal Society from 1898 to 1919.

We regret to record the death on April 19, at seventy years of age, of Sir Alfred Pearce Gould, K.C.V.O., late vice-chancellor of the University of London, and president of the Medical Society of London and of the Röntgen Society.

Current Topics and Events.

At the meeting of the London Mathematical Society to be held on May 11, at 5 p.m., in the rooms of the Royal Astronomical Society, Burlington House, Prof. G. H. Hardy will deliver a lecture on "The Elements of the Analytic Theory of Numbers." Members of other scientific societies will be welcome.

The Institute of Physics, of which Sir J. J. Thomson is president, is arranging for the delivery of a course of public lectures with the view of indicating the growing importance and place which physics now holds in industry and manufacture. The first of these lectures was delivered by Prof. A. Barr of Glasgow, on Wednesday, April 26, in the Hall of the Institution of Civil Engineers.

Rai Bahadur Sarat Chandra Roy is carrying on with a considerable measure of success his new quarterly journal of anthropology, entitled *Man in India*. The third number contains two important articles by Mr. T. C. Hodson, the author of works on the Nagas and other Assamese tribes, on exogamy in India and free marriage, which merit the attention of anthropologists, besides shorter notes on the Kharwars and Khasis and on Indian palæoliths. The journal, which is published at Church Road, Ranchi, deserves encouragement.

A John Scott medal and certificate, with a premium of 160*l*., has been awarded by the Board of Directors of City Trusts, United States of America, to each of the following: Dr. William Duane, for "his researches in radio-activity and the physics of radium and of X-rays"; Prof. R. A. Fessenden, for "his invention of a reception scheme for continuous wave telegraphy and telephony"; Mr. Elwood Haynes, for "his discoveries in connection with stainless steel, stellite, chrome-iron, etc."; and Dr. T. B. Osborne, for "his researches on the constitution of the vegetable proteins."

The annual meeting of the Iron and Steel Institute will be held on May 4-5 at the house of the Institution of Civil Engineers. On the first day of the meeting, the new president, Mr. Francis Samuelson, will deliver his presidential address, and the Bessemer Medal will be presented to Prof. Kotaro Honda. The remainder of the meeting will be devoted to the discussion of some thirteen papers by various workers on the constitution, properties, and manufacture of iron and steel. The annual dinner of the Institute will be held on May 4 at 7.30 p.m. at the Connaught Rooms, Great Queen Street, W.C., and the autumn meeting will be held in London on September 5-7 next.

MR. JOHN PLACE, 16 The Avenue, Beckenham, Kent, directs our attention to a phenomenon known to the guides at the Solfatara of Pozzuoli near Naples, but not, as he believes, satisfactorily explained. When a lighted torch of brushwood or tarred string is introduced into, or merely waved near any of the crevices from which gases emanate, the emanation appears to be greatly increased and "smoke and steam issue from the spot where the torch is waved," and even from fissures at a considerable distance. We suggest that the burning of the torch provides nuclei for condensation of vapour; for clouds gathering in a volcanic crater have been traced, in some cases at least, to atmospheric vapour influenced by the fine ejecta from the vent.

THE issue of the index numbers of the physics and electrical engineering sections of *Science Abstracts* completes volume 24 of each. The physics section extends to more than 900 pages, 800 of which are occupied by 2000 abstracts, while the electrical engineering section of 650 pages devotes 600 pages to nearly 1200 abstracts. Both volumes are rather larger than pre-war issues, while the number of abstracts is approximately the same. The increase of length of the abstracts is scarcely justified by any increase in the intrinsic importance of the matter abstracted. The greater average length of the electrical engineering as compared with the physics abstracts is due mainly to the number of descriptions of power plants and installations. *Science Abstracts* continues to be one of the most valuable and time-saving publications issued in this country; without it, research in physics and electrical engineering would be seriously hampered and progress retarded.

THE issue of *Science* of March 31 contains an account of the opening of the Norman Bridge Physics Laboratory of the Californian Institute of Technology at Pasadena, South California. The laboratory and equipment have been provided by Dr. Norman Bridge with the object of furthering work of the highest type in the mathematical and physical sciences and their applications. In the opinion of Dr. Millikan no subject furnishes a better training in accurate observation, honest and dispassionate treatment of data, and logical deduction of consequences, while the classics are gradually disappearing as the foundation of the American educational system. The physics laboratory, of which Prof. Millikan has been appointed director, and the Gates Chemical Laboratory with Dr. Noyes as director, are to receive 7000*l*. per annum for five years from the Carnegie Corporation, and will thus be able to co-operate with the Mount Wilson Observatory in a joint investigation of the constitution of matter and the nature of radiation.

IN a paper read at a recent meeting of the Royal Colonial Institute, Mr. J. M'Whae, Agent-General for Victoria, dwelt on the importance of white settlement of the "heart of Australia," an area of over half a million square miles lying approximately within a circle of 400 miles radius, the circumference of which passes through Sydney, Melbourne, and Adelaide. This area at present contains only 3,300,000 inhabitants, although it comprises as great an area as France, Germany, Denmark, Switzerland, Holland, and Belgium together. He admitted, however, that the problem is not merely one of attracting population but depends also on the provision of a sufficiency of water. Artesian wells number over 5000, and there are in addition many shallow bores in the Riverina. In Victoria to-day 14,000,000 acres out of 56,000,000 acres are being artificially irrigated. The Murray river valley offers the greatest opportunities and considerable areas of arid land have been reclaimed. The greater part of the "heart of Australia" must, however, depend on artesian water, and to what extent this supply is inexhaustible remains to be seen.

THE annual report of the Smithsonian Institution of Washington for 1919 is a volume of nearly six hundred pages, of which the greater part is composed, as is customary, of noteworthy contributions to science which were made known during that year. In all, twenty-eight such publications are included. Sir Ernest Rutherford's article, "Radium and the Electron," which appeared in the Jubilee issue of NATURE of November 6, 1919, and Sir Arthur Keith's presidential address at the Bournemouth meeting to Section H (Anthropology) of the British Association on "The Differentiation of Mankind into Racial Types," from NATURE of November 13, 1919, are reprinted. There are also two translations, "On the Extinction of the Mammoth," by H. Neuville, which is taken from *L'Anthropologie* of July 1919, and "A Great Chemist: Sir William Ramsay," by Ch. Moureu, from *Revue Scientifique* of October 1919. Some of the remaining papers are reprinted from American journals and a few are original. The volume forms a valuable record of notable announcements in the world of science for the year 1919.

WE have received from Messrs. Harbutt's Plasticine, Ltd., of Bathampton, an inexpensive outfit for mounting insects and other natural history objects. The apparatus is very simple and consists of "thymo-plas," which is plasticine impregnated with a strong preservative, slides of celluloid, and binding strips of gummed paper. In using this method, a narrow strip of "thymo-plas" is used to form a cell of the desired shape on the centre of a celluloid slide: the object to be mounted is then transferred to the cavity thus formed and a second slide of celluloid is pressed down on top. The opposite ends of the two superposed slides are securely bound together with strips of gummed paper, and the mount is then complete. The paper strips also serve as labels upon which the necessary data relating to the specimen may be recorded. Any one who tries this method will find no difficulty in carrying it out; groups of insect eggs *in situ* on leaves or twigs, coccids, larval tubes, cocoons, pupæ, etc., can all be well exhibited when mounted in this way. The method can also be applied to samples of seeds, fibres, small shells, and many other objects. In so far as adult insects are con-

cerned the specimens are not so well displayed as when pinned and set, but, on the other hand, they are secure against damage, and the "thymo-plas" method should be valuable for teaching purposes when specimens must of necessity be handled frequently. Collections mounted in this manner can be stored in microscope slide cabinets with undivided trays. By way of advertisement it is stated that "thymo-plas" is "adopted by Prof. Lefroy as the standard method for use in the Entomological Department, Royal College of Science, London." The price of the outfit is 3*s.* and 6*s.* according to size.

Two catalogues of second-hand works of science, each of exceptional interest, have recently reached us, namely, Sotheran's Catalogue of Science and Technology, No. 3, and Heffer's Catalogue (No. 210) of Scientific Books and Publications of Learned Societies. In the former list many works from the libraries of the late Profs. Carey Foster, J. Perry, and P. Duhem are offered for sale. In the latter a prominent feature is sets of scientific journals. The catalogues are obtainable free of charge from their respective publishers—H. Sotheran and Co., 140 Strand, W.C.2, and W. Heffer and Sons, Ltd., Cambridge.

Our Astronomical Column.

THE APRIL METEORS, 1922.—Mr. W. F. Denning writes that what appears to have been the most brilliant and abundant shower of Lyrids observed during the present century was witnessed by Miss A. Grace Cook and Mr. J. P. M. Prentice, of Stowmarket, on the night following April 21. Miss Cook, watching the sky up to 13 hours G.M.T., observed 30 Lyrids, and a number of others must have escaped observation while the paths of the brighter meteors were being recorded. Eight of the meteors seen were brilliant, six of them being estimated as equivalent to, or surpassing, the lustre of Jupiter. The maximum of the display apparently occurred in the two hours preceding midnight; the meteors moved swiftly, leaving trails. The brightest object appeared at 11 h. 12 m. G.M.T., and it left a conspicuous streak which remained visible for twenty seconds. Mr. Prentice also watched the progress of the shower, and saw many brilliant meteors, though the sky was partly clouded at times.

At Bristol the sky was overcast during the whole night, and no meteors could be seen.

ECCENTRICITY OF DOUBLE-STAR ORBITS.—Prof. H. N. Russell shows (*Pop. Ast.*, March) that it is possible to deduce average eccentricities, by statistical methods, even in the case of those long-period systems in which only a very small portion of the orbit has been described. All that is necessary is to note the angle between the tangent and the radius-vector, and compare the observed distribution of angles with that resulting from different assumed values of eccentricity. From observations of 750 pairs he deduces a mean eccentricity slightly greater than 0·6, about the same as that given by stars the orbits of which have been determined. This is an important result from the cosmogonic point of view, as the orbits now considered must be very large, and the periods measured by millenniums.

PROGRESSIVE LATITUDE CHANGES.—The reported change of the latitude of the International Station at Ukiah, California, at the rate of a foot a year, recently attracted considerable notice. Prof. F. Schlesinger devotes an article to the subject in *Astr. Journ.*, 798. He notes that Cohn's proper motions (depending on the Auwers system) are used for the latitude stars at the International stations, and that they differ systematically from those of Boss. The following list shows the apparent annual change of latitude of the six stations—(1) using Cohn's system and (2) using Boss's: Mizusawa, Long. $-141°$ (1), $+0·0008''$ (2), $-0·0079''$; Tschardjui, Long. $-63°$ (1), $+0·0110''$ (2), $+0·0023''$; Carloforte, Long. $-8°$ (1), $+0·0053''$ (2), $-0·0034''$; Gaithersburg, Long. $+77°$ (1), $+0·0103''$ (2), $+0·0016''$; Cincinnati, Long. $+84°$ (1), $+0·0099''$ (2), $+0·0012''$; Ukiah, Long. $+123°$ (1), $+0·0106''$ (2), $+0·0019''$. It will be seen that the systematic northward shift resulting from Cohn's values vanishes when Boss's are used. If we ascribe the changes to a motion of the pole, the indicated motion is 5 inches per annum towards North America. We may, however, consider that at Mizusawa, which is in a volcanic region, there is an actual surface shift of 10 inches per annum southward; the shifts at the other stations are small enough to be regarded as accidental. Prof. Schlesinger urges that observations at the second, fourth, and fifth stations, which were dropped during the war, should be resumed, at least temporarily.

EFFECTIVE TEMPERATURES OF STARS.—Various methods used to obtain stellar temperatures give different results, yet it is interesting to note that the divergences are not great; indeed, for stars of classes G, K, and M, stars of comparatively low temperature, the agreement is fairly close. The cause of these disagreements lies probably in the fact that each observer has limited himself to a portion of the spectrum only, which may not necessarily contain the observed maximum spectral energy. Dr. W. W. Coblentz, in the Proceedings of the National Academy of Sciences (U.S.A.) (vol. 8, No. 3, p. 49), gives the results of his inquiry into the effective temperatures of 16 stars as estimated from the energy distribution in the complete spectrum.

By means of screens of red and yellow glass, quartz, and water he found it possible to obtain the radiation intensity in the spectrum in consecutive portions from $0·3\mu$ to 10μ. In addition to an interesting table giving a comparison of the total radiation from stars having closely the same visual magnitude but of very different spectral class, Dr. Coblentz sums up his results in another table, comparing his stellar temperatures with values previously obtained by other workers. As the values he has deduced will prove very useful for reference they are here reproduced, commencing with the hottest stars and passing through the various stellar types, taking class Go as standard.

Star.	Spectrum Type.	Temp.
ε Orionis	Bo	13,000° K
β Orionis	B8p	10,000
α Lyræ	Ao	8,000
α Can. Maj.	Ao	8,000
α Cygni	A2	9,000
α Aquilæ	A5	8,000
α Can. Min.	F5	6,000
α Aurigæ	Go	6,000
α Bootis	Ko	4,000
β Geminorum	Ko	5,500
α Tauri	K5	3,500
α Orionis	Ma	3,000
α Scorpii	Ma p	3,000
β Androm.	Ma	4,000
μ Geminorum	Ma	3,500
β Pegasi	Mb	3,000

Research Items.

THE DISPERSION OF FLIES BY FLIGHT.—A definite knowledge of this subject is of importance in measures of control or repression. It is also of significance in the study of the spread of fly-borne diseases. Messrs. Bishopp and Laake (*Journ. Agric. Research*, xxi. No. 10, Aug. 15, 1921) have conducted an extensive series of observations with several species of common flies, using an estimated total number of 234,000 specimens in the experiments. These were marked by being liberated into bags containing finely powdered red chalk or paint pigment, and afterwards allowed to escape. In order to ascertain the distance of dissemination, baited fly-traps were set at measured distances, in different directions, from the point of liberation. The experiments carried out show that under rural and urban conditions flies have marked powers of diffusion; similar results obtain for both the sexes, although in very different proportions in different species. The common house fly, *Musca domestica*, was recaptured at a distance of more than 13 miles from the point of liberation, *Chrysomya macellaria* 15 miles, and *Phormia regina* nearly 11 miles. The fact that many favourable feeding and breeding grounds were passed over by the flies appears to indicate that, in so far as the above three species are concerned, very evident migratory habits are noticeable. The authors conclude that, under natural conditions, the influence of moderate winds on dissemination is not of great importance. The speed of flight is evidently considerable; thus *Phormia regina* was recovered about 11 miles away in less than 48 hours after release, and *Musca domestica* travelled over 6 miles in less than 24 hours. The stimuli affecting dispersion appear to be so blended and mixed as to make it impossible to judge their relative importance.

THE ASCENT OF SAP.—Sir J. C. Bose informs us that he has carried out a series of investigations at the Bose Institute, Calcutta, which affords a complete explanation of the phenomenon of the ascent of sap, and its diverse manifestations. The following is a short summary of the results: (1) It is shown that the ascent of sap is a process of physiological activity dependent on the pulsation of living cells inasmuch as it is arrested by the action of poison, either in entire plants or in cut shoots. (2) The active pulsating cells are not confined to the root, but are continued throughout the stem. It has been ascertained that in the stem of Dicotyledons, these cells constitute the cortical layer which abuts upon the endodermis. (3) The velocity of the ascent has been determined by three independent methods, which give concordant results. The ascent takes place in plants even in the complete absence of transpiration. In "varnished" plants this velocity has been found sometimes to be as high as 70 metres per hour. (4) The cellular pulsations have been investigated and their characteristics determined from automatic records; they consist of alternate contractions and expansions. (5) The direction of propulsion is determined by the phase differences of the adjacent cells. The velocity increases with the wave length of the propagated impulse. This wave length is determined experimentally from definite points of electric maxima and minima. Enhancement of velocity is associated with corresponding increase in the wave length. (6) The enhanced rate of ascent is also attended by the increase of amplitude and frequency of cellular pulsations. (7) Ascent of sap depends upon cellular pulsation in tall trees as well as in herbaceous plants. There is, however, in the former the special adaptation of the woody tissue which serves as a reservoir to meet the excessive demand for water in the season of active transpiration. When this reservoir is more or less depleted, the phenomenon of "negative pressure" is manifested.

NORWEGIAN EXPLORATIONS IN SPITSBERGEN.—In 1917 the Norwegian Government decided to undertake the systematic survey and exploration of the western part of the mainland of Spitsbergen between Ice Fjord and the South Cape. This was in continuance of previous Norwegian work under the auspices of the Prince of Monaco on the west coast between the north of Spitsbergen and Ice Fjord. The work was to include geological exploration and hydrographical survey in coastal waters, where this was incomplete. In "Revue de Geographie Annuelle," Tome ix., Fascicules iv.-v., 1922, Mr. A. Hoel gives a full account of the surveys made in 1919, 1920, and 1921, when he was in charge, and a summary of the whole work, which is now virtually completed after five summers in the field. Only a few small gaps in the survey between Horn Sound and the South Cape remain to be filled in. Altogether some 4800 sq. kilometres of land surface have been surveyed. The most striking geological results are the proof of the Ordovician age of the Hecla Hook beds of the west coast, and the discovery that beds ranging from Carboniferous to Tertiary ages form the greater part of the coastal region south of Horn Sound where the Hecla Hook beds were supposed to predominate as they do farther north. The botanical researches, of which some important results have already been published, promise to be of great interest.

TERTIARY FOSSILS OF PERU.—We have received a copy of "Illustrations of the Tertiary Fossils of Peru," by H. Woods, T. Wayland Vaughan, and J. A. Cushman. It consists of twenty-four plates of fossils and their explanations, without any indication of the source of issue or the possibility of accompanying text. We understand, however, that they are intended to illustrate a forthcoming work on the "Geology of N.W. Peru," by Dr. T. O. Bosworth. The first twenty plates deal with Mollusca, and for these Mr. Woods is responsible, Mr. Vaughan answering for three of Corals, and Mr. Cushman for the one of Foraminifera. This separate issue will be very welcome to palæontological students, who will at once recognise the wonderful similarity of these Peruvian fossils to those of our British Oligocene and Eocene; indeed one, *Venericardia planicosta*, is said to be identical, while there is a Clavilithes, which the author, doubtless on good grounds, cites as a new species, but which one might be forgiven for mistaking for *C. longævus*. Mr. T. A. Brock, the draughtsman of the plates, is to be congratulated on his beautiful figures, which have been most admirably reproduced: we have seen nothing better.

RECORDS OF PALÆONTOLOGICAL RESEARCH.—It is well from time to time to emphasise the value of the simple paper-bound guides to the British Museum collections as means of keeping the student in touch with the developments of research. The tenth edition of "A Guide to the Fossil Reptiles, Amphibians, and Fishes" has just appeared, with 8 plates and 117 text-figures, price 2s. (1922). Here will be found the Downtonian ostracoderms of Lanarkshire, the problematic Palæospondylus, Ichthyosaurus from Lyme Regis, clothed in a habit drawn from German specimens, and Tritylodon, placed clearly with the theriodonts. One of the plates shows the immense proportions of the hind limb and tail of the Cetiosaurus discovered by A. L. Leeds near Peterborough.

The Limbs of Trilobites.—Those zoologists and palæontologists who have been fortunate enough to look through P. E. Raymond's recent monograph on the trilobites (see Nature, vol. 108, p. 481) will be glad to note Dr. C. D. Walcott's additions, comments, and suggestions as to limb-structure, in his recent paper on the Cambrian Neolenus (Smithsonian Misc. Coll., vol. 67, No. 7, 1921). The author proposes to put forward the results of further investigations into the organisation of trilobites "in the course of two or three years," so that our anticipations when directing attention to the stimulating nature of Raymond's paper were evidently correct.

Geology for Townsmen.—The Geological Survey of Great Britain has done great service to those who dwell or work in London by issuing a memoir by H. Dewey and C. C. A. Bromehead on "The Geology of South London" (Ordnance Survey, Southampton, 1921, price 3*s.* 6*d.*). This describes the country covered by the recent colour-printed map, showing superficial deposits, Sheet 270, on the scale of 1 : 63,360. Starting from the gravels of Ealing, Hyde Park, and Millwall on the north, we can realise, as in a series of pictures, the broad exposures of London clay south of the Thames, supporting at Wimbledon outliers of Glacial gravel; and in the south we reach the chalk at Sutton, and rise to the unspoiled uplands of Banstead Downs and Sanderstead. The geological colouring well marks out the old valley, widening quickly on the clay, by which the railways now reach Croydon from the south. The memoir contains a view of the area in 1794, looking across London from the north, and another of Richmond at about the same date. The sources of these should have been mentioned; they appear to be from separately published plates. A city and suburban map, of equal interest, but of a very different nature, is the Johannesburg Sheet (52) of the Geological Survey of South Africa. The scale is near 1 : 150,000. With the attached longitudinal section, it is an admirable exposition of the geological relations of the Witwatersrand system, and the moderate price of 5*s.* includes a memoir by C. T. Mellor and A. L. Du Toit (Pretoria, 1921). The area covers the whole historic mining district, and extends across the dolomite to the reappearance of the Rand rocks at Heidelberg.

Electrification of Phosphorus Smoke Nuclei.—With reference to a note on electrical precipitation which appeared in Nature of March 23, p. 388, we have received a paper by J. J. Dowling and C. J. Haughey (Proceedings of the Royal Irish Academy, vol. 36, Section A, No. 3) on the electrification of phosphorus smoke nuclei. The authors' experiments indicate that the nuclei in the smoke of phosphorus slowly oxidising in air acquire charges in an electric field, that the charges depend on the strength of the field, and that they vary in whole multiples of the electron. Charges from one to twenty-five electrons were observed. They also indicate that when large numbers of particles, of nearly equal sizes and charged equally, are exposed to the same electric field, the particles may be dragged through a comparatively narrow channel in the air, and may carry the air in this channel along with them. The mobilities of particles in fumes exposed to electric fields may, therefore, exceed considerably what might be expected for the limiting velocity according to Stokes's law applied to isolated particles (as in the well-known experiments of Millikan). This effect is obviously of importance in precipitation apparatus, and careful quantitative experiments of this kind should be of assistance in the design of such apparatus.

A New Science Microscope.—We have received from Mr. C. Baker of 244 High Holborn, W.C.1, an example of his new Science Microscope which has been specially designed to meet the requirements in science schools (Fig. 1). The stand is a single casting with a foot of the horse-shoe type but with a posterior limb which gives complete stability. A large square stage, 4·2 in. × 4·2 in. is provided with mirror below, with plain and concave surfaces. The coarse adjustment, of the diagonal rack and pinion type, gives a motion slow enough to enable the user to focus with comfort a $\frac{1}{6}$-in. objective—actually we found that even a $\frac{1}{12}$-in. objective could be used without difficulty. A combination 1 in. and $\frac{1}{6}$ in. objective was supplied and both powers were found to give excellent definition and flat field. The instrument is well finished, rigid in all parts and strongly built, and should prove a very serviceable one capable of withstanding rough usage. For the stand alone the price is 4*l.* 10*s.*, or with a No. 3 eyepiece and combination 1 in., $\frac{1}{2}$ in. and $\frac{1}{6}$ in. objective, 6*l.* 17*s.* 6*d.* In this particular instrument, the objective thread did not seem to be exactly the R.M.S. standard size, for we were unable satisfactorily to attach a Zeiss, a Leitz and four Swift lenses, which themselves were completely interchangeable on their respective instruments.

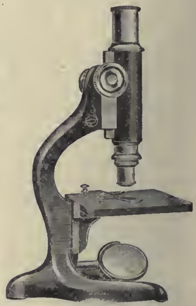

Fig. 1.

Thermometers for measuring Rock Temperatures.—An interesting new type of thermometer has recently been designed and constructed by Messrs. Negretti and Zambra, for the purpose of measuring the surface temperature of rocks, sand, or other materials. Since the difficulty in design lies in securing that the bulb shall take up accurately the temperature of the surface, whatever the other attendant circumstances may be, the new features of the instrument mentioned are associated with the bulb end of the thermometer. The other end of the thermometer is simply supported so that the stem, which is about 15 cm. long, lies parallel to the surface and about 0·5 cm. from it. At the bulb end the stem is curved so that the bulb (of rather larger size than in a clinical thermometer) lies along and almost touching the surface. Actual contact is effected by a thin flat copper plate lying on the surface and attached to the bulb, which itself is copper-plated on the outside. The under surface of the plate is roughened, and its relatively large surface (it is about 1 cm. wide) quickly takes up the temperature of the rock by conduction and radiation, and conducts the heat rapidly to the glass bulb. The upper surface of the plate, and the plated surface of the bulb, are polished to prevent radiation to or from the surrounding objects. The bulb is further insulated by a polished reflector which covers it almost entirely, and prevents radiation while also reducing conduction of heat by air currents. The reflector is gilt in order that it shall not become tarnished. The mass of the bulb is small, so that it possesses little thermal capacity and scarcely disturbs the condition of temperature existing before placing the bulb on the rock; the thermal inertia is also small for the same reason. The makers state that on holding the bulb near to the side of the radiator with the polished surface facing the radiator, the thermometer shows no change of reading, but on turning it round so that the flat copper plate faces the radiator, the column at once begins to move.

The Aryan Problem.

ON March 28, Mr. Harold Peake made a communication to the Royal Anthropological Institute on the subject of Bronze Swords and the Aryan Problem. He began by describing a type of sword, with a long tang cast to fit the hand, the Type II. of Naue, which is believed to have originated in the Danube basin. He showed how the butt of the blade had passed from a depressed semicircle through various forms to that of a flattened oval, and how its convex outline had then gradually become concave; he then divided the swords into a progressive series of seven types. He explained how the first of these had developed from a dagger, while the last had been found in the Hallstatt cemetery, where iron weapons had been the rule.

Mr. Peake next considered the distribution of the series, showing that type A was of Hungarian origin; type B ranged thence northwards to Denmark; type D was found in Greece and Egypt and in certain regions of Italy; type E ranged across France, England, and Ireland; type F was absent from Hungary and was confined to the mountain region of central Europe; while type G, the Hallstatt type, was also absent from the Hungarian plain but widely distributed to the west and north.

It was suggested that the Egyptian specimens were relics of the Ek-wesh, who invaded Egypt in 1220 B.C., and that those from Greece had been introduced by the Achæan invaders, who were, Mr. Peake thought, only a few wandering heroes, of Thraco-Phrygian origin, who made themselves masters of city states in Greece. This gave an approximate date to type D of 1250–1150 B.C., while type G could not be earlier than 1000–900 B.C.; he suggested that type A was evolved after 1400 B.C.

It was argued that the distribution of these swords must be referred rather to invasion than to trade, and it was suggested that peoples emerging from the Hungarian plain and adjoining mountain regions had passed thence, in 1350 to Denmark, in 1250 to Greece and Italy, and in 1150 to France and Britain.

Mr. Peake then discussed the absence of types F and G from Hungary, and showed evidence of the departure of some of these people through the Dukla pass, across Galicia and Podolia to the Koban. He showed how they learnt the use of iron from tribes on the southern slopes of the Caucasus and suggested their return to Hungary with their new weapons. Some of these invaded Greece as Dorians, while others pressed up the Save to the iron-fields and to Hallstatt for the salt-mines; they destroyed the lake-dwellings in the mountain zone, whence refugees fled down the Rhine to Holstein, to the east of England and to Ireland, while others passed through the Belfort gap into France and thence down the Rhone, Loire, and Seine. Other invaders crossed the Predel pass into Italy, destroyed the *terra-mara* culture of the Po Valley, and settled north of the Apennines near Bologna, introducing the Villanova culture, while others again passed by the old route into France, and followed the refugees down the Rhone and Loire but not down the Seine.

Thus there were two movements of peoples allied but in some ways distinct. The first waves had bronze swords and included the refugees from the lake-dwellings of the mountain zone; the second wave had iron swords and were the Dorians, Villanova, and Hallstatt peoples.

Turning to the linguistic side, Mr. Peake sketched in outline the Aryan hypothesis and referred to a paper published in 1891 by Sir John Rhys. In this paper it was suggested that two waves of similar people had dispersed from central Europe, westward and southward, the first speaking Q and the second P tongues. To the first belonged Gaelic, Erse, Latin, and Ionic Greek, to the second Welsh, Osco-Umbrian, and Greek. Sir John Rhys had suggested that the second wave consisted of non-Aryan people, probably from the Swiss lake-dwellings, who had learnt Aryan speech from their subjects.

Mr. Peake pointed out that Sir John's theory had not been well received, especially in Germany, and that certain of his conclusions could not be accepted. The Ionic dialect of Herodotus was not an archaic form, though perhaps Thraco-Phrygian might represent the Q form of Greek speech. Again, evidence was against the Swiss lake-dwellers being the conquering labialisers. Still archæology showed evidence of two dispersals, and it might be that Sir John's theory was correct in the main though erroneous in some of its details.

The case was tested in Italy, where Mr. Peake showed that the bronze swords were confined to a definite region, mainly around Fucino, while the Villanova culture centred chiefly north of the Apennines. He exhibited a map of the Latin or Q dialects, which coincided very nearly with the distribution of the bronze swords, except in one or two particulars, and to account for these he related a story told by Dionysius of Halicarnassus how the Aborigines dwelt in this area, but one night the Sabines, a P people, issuing from Amiternum, dislodged some of them, who eventually marched towards Rome and settled there.

Mr. Peake suggested that the Italian test seemed to prove that so far as this peninsula was concerned the archæological and philological evidences agreed. In Greece the first wave consisted of a few heroes only, the second wave was the only true invasion; here, as would be expected, we had only P speech. In France both waves covered the same ground, except that in the valley of the Seine the latter was lacking. It was in this valley that we had the best evidence of Q speech in Gaul, the river Sequana and the tribe Sequani. He maintained, therefore, that the equations all round were as clear as could be expected, and that the main features of Sir John Rhys' hypothesis were justified.

British swords for 25 years and that he agreed with

Mr. Parker Brewis said that he had been studying the typological scheme proposed by Mr. Peake. He was also prepared to accept the dates, though type G lasted in Britain to a much later date. Mr. E. C. R. Armstrong also agreed with the typology and chronology, but said that the philologists of Dublin would not accept the view that the Q people had ever settled in England.

After some remarks by Mr. Parkyn, Mr. Peake replied that his chronology referred to central Europe and not to Britain, and that he was well aware of the views of the Dublin philologists. He was prepared to admit, at any rate for the sake of argument, that there was no linguistic evidence for the early presence of Q people in England, but that such negative evidence was not conclusive in the light of the positive evidence he had adduced. At the request of the chairman, Dr. A. C. Haddon, he then outlined his views on the racial affinities of the people he had been discussing, and on the original dispersion of the Aryan people.

Woollen and Worsted Research.

THE annual report of the Council of the British Research Association for the Woollen and Worsted Industries for the year 1921 gives details of the progress which the Association is making, and includes some lines of its future activities. The Association is now in its fourth year, though it is only during the past year that its building and equipment have been sufficiently completed to furnish the research staff with reasonable facilities for extensive development of its work. The main activities of the Association during the year have resulted from the work of the research, education, and sheep-breeding committees of the Council of the Association, on which expert advisory members are co-opted.

As the publications of the Association are circulated to its members only, and to certain allied associations and institutions, it is difficult to estimate the actual extent of the work of the Association. One interim report has, however, been published dealing with faults caused by oils, effect of light on oil stains, photomicrographic work on raw wool, standard conditions for measuring wool fibre diameters, cross-sections of wool fibre, polarity of the worsted sliver, construction and control of the humidity room, and the effect of oil stains on dyeing. Two reports including observations on the elasticity and setting of wool by time, heat, and moisture, and work on the dyeing and burldyeing of union cloths have also been published. In view of its importance in the textile industry, it is surprising to find that the effect of light on the oils themselves does not appear to have been studied.

Reports are also in preparation on the fastness of dye-stuffs on woollen material, the sorption of neutral soap by wool and its bearing on scouring and milling processes, and on the methods of estimation and analysis of soap in cloth and yarn. In addition the research committee has sketched out a bold and comprehensive programme of research. The programme includes problems presenting themselves in most sections of the textile trade, and of its allied branches. The committee has obviously attempted to avoid "the short-sighted policy of confining research organisations to the search for results of immediate commercial value," and if results in some only of the branches named in the programme are forthcoming in future years, the Association should render help of the greatest value to the industry.

The education committee of the Association has been active in its efforts to co-ordinate textile educational work. As a result of a joint meeting with the Board of Education, the National Wool (and Allied) Textile Industrial Council, and the City and Guilds of London Institute, a Joint Advisory Education Committee has now been formed, which will assist the Board of Education and the City and Guilds of London Institute in textile educational matters. The education committee of the Association has itself drawn up syllabuses of textile courses, and has secured the provision of some research fellowships for textile work.

Coal Resources of South Africa.

UNDER the title "Recent Additions to our Knowledge of the South African Coalfields," Dr. E. T. Mellor has contributed a paper to the Transactions of the Geological Society of South Africa, vol. 25, which supplies a much-needed summary of the coal resources of South Africa.

The Witbank or Middleburg coalfield is the most important, and owing to the fact that it is comparatively readily accessible to the main line of the Transvaal-Delagoa Bay railway, it has been more extensively worked and more thoroughly prospected than any of the others. It is comparatively free from disturbances of any great importance, and the continuity of the seams has now been fairly well proved for a length of some 45 miles. There are five and in places six seams, the two most important being the No. 2 Seam, averaging 16 to 20 feet in thickness, and the No. 4 seam, averaging 24 feet, and in places reaching a thickness of 27 feet. All these coals are somewhat variable in character, there being some areas, fortunately quite extensive, in which the coal is of good quality with a relatively low ash, whilst in others the ash is much higher, owing, according to the author, to certain conditions that prevailed at the time of its deposition. In one block of 7000 acres, a tonnage of over 214 million tons has been proved, and the whole field is estimated as being capable of yielding at least 1000 million tons of coal of an evaporative power of 12·5 or over.

The Komatipoort coalfield has disappointed the expectations that were at one time formed of it and, in Dr. Mellor's words, "its prospects as a coalfield must be regarded as very doubtful."

In Swaziland recent boring operations have proved the existence of several seams, mostly thin, of coal of high quality, though the total tonnage likely to be developed does not at present appear to be very considerable.

In the Waterberg district several seams of good coal have recently been discovered, but owing to the distance from any line of railway, this field cannot be looked upon as of any value in the immediate future.

The Natal coalfield differs in many respects from that in the Witbank district; the coal seams are thinner, rarely exceeding 5 feet, and they have been broken up and greatly affected by intrusions of dolerite. Moreover, they lie relatively deep, and for these reasons are gassy and present greater working difficulties than the coal of the Transvaal field. The quality of the coal is good, but the prevailing impression as to the available quantity appears to be greatly exaggerated. It is now estimated that the best Natal coal is likely to be exhausted in another 40 or 50 years.

These statements show that the Witbank coalfield must be looked upon as the main source of South African coal supplies, and this field presents numerous advantages, amongst them being the shallowness of the seams and the ease with which they can be worked. South Africa may therefore be reasonably expected to become a formidable competitor in the world's coal markets, and to develop an important coal export trade. Coal is also likely to play an important part in the development of local industries, amongst which iron manufacture will probably be one of the most important. The main obstacles at present are the inadequacy of railway transport to the coast and the want of proper shipping facilities. It is obvious that both of these difficulties can easily be overcome, and when they are, South Africa will be ready to take full advantage of this additional source of wealth.

H. L.

A National Council for Mental Hygiene.

A GENERAL meeting will be held at 5 o'clock on Thursday, May 4, in the rooms of the Royal Society of Medicine, Wimpole Street, in order to decide on the constitution, officers, etc., of the new National Council for Mental Hygiene. The provisional committee consists of Sir Courtauld Thomson (chairman), Sir Norman Moore, Sir Charles Sherrington, Sir John Goodwin, Sir George Newman, Sir Walter Fletcher, Dr. C. H. Bond, Dr. Bedford Pierce, Prof. George Robertson, Dr. C. S. Myers, Dr. G. Ainsworth, Dr. Helen Boyle, Dr. Edwin Bramwell, Dr. Farquhar Buzzard, Sir Maurice Craig, Lord Dawson of Penn, Sir Horatio Donkin, Prof. Elliot Smith, Dr. Edwin Goodall, Dr. Henry Head, Dr. Crichton Miller, Sir Frederick Mott, Dr. W. H. R. Rivers, Sir Humphry Rolleston, Dr. T. A. Ross, Dr. Tredgold, and Dr. W. Worth.

A letter, signed by Sir Courtauld Thomson, appeared in the *Times* of March 29 which describes the purposes for which the new Council is being established. It will co-ordinate and encourage the work of the various existing societies which are "engaged in promoting the study of mental disorders, the welfare of the insane, the problems of industrial psychology and the various aspects of mental deficiency"; it will also aim at establishing psychological clinics in general hospitals for the early treatment of mental disturbance, and at improving the education of the medical student in normal and abnormal psychology. In addition, it will attempt to lessen the popular ignorance at present prevailing in regard to the nature and prevention of mental illness, which results in an enormous amount of needless unhappiness and wastage of energy.

Such National Councils have been and are being formed in various countries on the Continent, moulded largely according to the pattern of the well-known United States National Committee for Mental Hygiene, which has done so much to raise the standard of the care and treatment of mental disorders in America, and to remove the widespread prejudice of the public towards these diseases. In America it has given birth to smaller Societies for Mental Hygiene in the various States and to an important Canadian Committee. Ample work awaits the formation of a National Council in Great Britain, and we extend to it the cordial welcome which it merits.

University and Educational Intelligence.

CAMBRIDGE.—The Report of the Financial Board on the expenditure of the current academic year points out that, despite the Emergency Grant of 30,000*l*., the University depleted its balances by 3975*l*. during the past academic year; and it is anticipated that there will be a further deficit of 7650*l*. in the current year. The Report of the Royal Commission has not come any too soon unless Cambridge is to increase its fees or to cut down its activities.

Mr. H. G. Carter has been appointed Curator of the Herbarium.

The Linacre Lecture will be delivered on Saturday, May 6, at 5.15 P.M., by Sir Humphry Rolleston, on the subject of "Medical Aspects of Old Age."

LONDON.—The following are among the Public Lectures to be given at University College during the present term:—"Atoms, Molecules and Chemistry," three lectures by Sir J. J. Thomson; "Insects and Disease," four lectures by Sir Arthur Shipley; "Recent Discoveries in Egypt," by Prof. Flinders Petrie; and "The Expansion of European Civilisation," four lectures, by Prof. W. R. Shepherd, of Columbia University. A copy of the full programme may be obtained by sending a stamped addressed envelope to the Secretary, University College, London, W.C.1.

IT is announced by the Royal Academy of Belgium that a prize of 1000 francs has been established, which will be awarded biennially, under the name of the Prix O. van Ertborn, for the best work on geology.

PROF. E. MELLANBY will deliver the Oliver Sharpey lectures at the Royal College of Physicians of London on Tuesday, May 2, and Thursday, May 4, at 5 o'clock. The subject of the lectures will be "Some Common Defects of Diet and their Pathological Significance."

THE Ramsay Memorial Trustees will, at the end of June, consider applications for two Ramsay Memorial Fellowships for chemical research. One of the Fellowships will be limited to candidates educated in Glasgow. The value of the Fellowships will be 250*l*. per annum, to which may be added a grant for expenses not exceeding 50*l*. per annum. Full particulars as to the conditions of the award are obtainable from Dr. Walter W. Seton, Secretary, Ramsay Memorial Fellowships Trust, University College, London, W.C.1.

NEW regulations have recently been made by the Trustees of the Beit Memorial Fellowships for Medical Research. The date of the election of Fellows has been changed from December to July, so that Fellows may commence work on October 1, instead of January 1, in each year. In future there will be three classes of fellowships, namely, (1) junior fellowships, 350*l*. per annum. Not more than six junior fellowships will be awarded annually. The usual tenure of a junior fellowship is for three years. (2) Fourth-year fellowships, 400*l*. per annum. On the recommendation of the advisory board, a junior fellowship may be extended for a further period of one year. (3) Senior fellowships, 600*l*. per annum. A limited number of senior fellowships may be awarded. The usual tenure of a senior fellowship is for three years. No change will be made in the emolument of any fellowship held at the date of coming into force of these amended regulations on May 1, 1922. All correspondence of candidates and fellows should be addressed to the Hon. Secretary, Beit Memorial Fellowships, 35 Clarges Street, Piccadilly, W.1.

THE annual report for the session 1920–21 of University College, London, contains some interesting facts which may well be placed on record. The total number of students enrolled for full time courses was 2408, of which 1506 were men; in addition there were more than 700 attending part time courses. In the full time courses, arts and science claim about equal numbers. During the year, donations to the College amounted to a little more than 3000*l*., a total which includes sums of 1500*l*. from the Carnegie United Kingdom Trust for the school of librarianship; 500*l*. from the Worshipful Company of Drapers, an annual grant to the biometric laboratory which will continue until 1924; and a grant of 250*l*. from the Chadwick Trustees for the departments of municipal engineering and hygiene. The London County Council made a capital grant of 5000*l*. towards the cost of the completion and equipment of the department of engineering. As in past years, the College has taken an active share in the promotion of adult education by the provision of free public lectures by men of note. In all, some seventy lectures and courses were given and it is estimated that more than 8000 persons attended.

Calendar of Industrial Pioneers.

April 27, 1885. Joseph d'Aguilar Samuda died.—Entering into partnership with his brother Jacob, Samuda built marine engines, laid down railways worked on the atmospheric principle, and became an eminent builder of iron steamships and armoured men of war. In his works in the Isle of Dogs he introduced labour-saving machinery, and with Reed, Woolley, Scott Russell, and others he helped to found the Institution of Naval Architects.

April 27, 1891. Loftus Perkins died.—Known for his bold experiment of fitting the yacht *Anthracite* with an engine supplied with steam at 500 lbs. pressure, and for his invention of the "arktos" cold chamber refrigerating apparatus, Perkins was the son of the inventor Angier March Perkins, and the grandson of Jacob Perkins, who came to England from America in 1827 and in 1828 constructed what was probably the first triple compound steam engine.

April 28, 1865.—Sir Samuel Cunard died.—The founder in 1839 of the famous British and North American Royal Mail Steam Packet Company, Cunard was a native of Nova Scotia. His first transatlantic liners were built on the Clyde, while the first passage was made in 1840 by the *Britannia*, a wooden vessel of 1154 tons and 740 horse power, which took 14 days 8 hours to cross. Iron steamers were introduced in 1855, and the paddle wheel abandoned for the screw in the early 'sixties.

April 28, 1914. Robert Kaye Gray died.—After passing through University College, London, Gray became an assistant to Charles Bright, subsequently superintended the laying of many important submarine cables for foreign governments, and became the head of the Telegraph Works Company at Silvertown. He assisted in founding the National Physical Laboratory and served as President of the Institution of Electrical Engineers.

May 1, 1895. John Newton died.—Graduating from the United States Military Academy in 1842, Newton was employed on engineering duties and saw active service during the Civil War. He was afterwards responsible for the improvement of New York harbour, and during the removal of the notoriously dangerous rocks at Hell Gate solved many new problems.

May 2, 1857. Frederick Scott Archer died.—The discoverer of the collodion process in photography, Scott started life as a silversmith and then became a sculptor. It was while trying to obtain pictures of his work that he made his noteworthy discovery.

May 3, 1888. Sir Charles Tilston Bright died.—A most eminent telegraph engineer, Bright in 1847 at the age of fifteen, through Cooke, entered the Electric Telegraph Company, and in 1856 with Brett and Cyrus Field initiated the movement for an Atlantic Submarine Cable. Appointed engineer to the Atlantic Cable Company he was on board the U.S.S. *Niagara*, which jointly with H.M.S. *Agamemnon* laid the first cable from Valentia to Newfoundland, and in 1858 he was knighted. Bright afterwards carried out important cable work in the Mediterranean, in the Persian Gulf, and in the West Indies. One of the original members of the Institution of Electrical Engineers, he served as president of the society in 1886–87.

May 3, 1909. Thomas Aldridge Weston died.—The inventor of many things, Weston was known all the world over for his differential pulley block and lifting tackle, a simple contrivance of great usefulness. Born in Birmingham in 1832 he was for a time associated with the firm of Tangye, but his later years were spent with the Brown Hoisting Machinery Company of Cleveland, Ohio. He died in New York.

E. C. S.

Societies and Academies.

LONDON.

Optical Society, April 6.—Sir Frank Dyson, president, in the chair.—H. H. **Emsley** and E. F. **Fincham**: Diffraction haloes in normal and glaucomatous eyes. Every normal eye, under appropriate conditions, sees diffraction rings or haloes encircling bright sources of light. Similar haloes are seen by eyes in certain abnormal pathological conditions, particularly in the case of eyes suffering from glaucoma. Tests are specified by means of which the different phenomena in the two cases may be identified.—E. W. **Taylor**: The effect of changes of surface curvature at the focus of an astronomical object glass. The balancing of the components of a large object glass is difficult, and the effect at the focus of a similar alteration of curvature at each of the four surfaces is different. If the effect of an alteration at each surface is known, the one most suitable may be chosen, having regard to the nature of the aberration to be overcome.

PARIS.

Academy of Sciences, March 27.—M. Emile Bertin in the chair.—The president announced the death of M. Louis Ranvier, member of the section of Anatomy and Zoology.—E. **Goursat**: A classical theory of Cauchy. Comments on two recent communications by M. Mittag-Leffler.—H. **le Chatelier**: The manufacture of soda with ammonia. A discussion by a graphical method of the bearing of some experiments of M. Toporescu (see below) on the ammonia soda process.—C. **Richet**, Eudoxie **Bachrach**, and H. **Cardot**: Studies on the lactic fermentation. Memory in micro-organisms. Culture of the lactic bacillus is made for one day in a medium containing traces of three poisons (arsenate, cadmium, copper) and then seven successive daily inoculations are cultivated on normal media. The strain of organism thus produced is sensitive to the action of each poison. The authors conclude that when two cultures of micro-organisms of the same species have lived, even for a short time, in slightly different media, they are different from each other.—C. **Lallemand**: The parabolic wage. The system of wage payment described, which has been tested in practice over a period of 34 years, is based on a formula $S = S_0 + kT^2$, where S_0 is the minimum wage, T the work done, S the actual wage paid, and k a constant. It is in effect a compromise between payment by time and by results. It has been applied in the "Service du Nivellement général de la France" since 1888, with the result that while the wage increased in four years from 6·30 francs to 12·25 francs, the cost per kilometre decreased from 40 to 33 francs.—P. **Montel**: A theorem of algebra.—G. **Giraud**: Non-linear partial differential equations of the second order of elliptic type.—P. **Lévy**: The *rôle* of the law of Gauss in the theory of errors.—E. **Cartan**: Generalised conformal space and the optical universe.—A. **Planiol**: Study of the friction losses in internal combustion motors. Experiments were carried out on a specially constructed 30 H.P. gas engine by three methods differing in principle. The results showed that the resisting couple of the motor due to friction was a linear function of the mean pressure shown by the indicator diagram. The constants obtained were shown to apply to another (35 H.P.) gas engine, and hence it is found possible to calculate the field of an internal combustion engine without taking indicator diagrams.—H. **Roussilhe**: The applications

of aerial photography and the photo-restitution apparatus.—H. **Chaumat**: A new wattmeter.—O. **Liévin**: The kinetic study of alkaline solutions of iodine. In alkaline solutions, iodine is transformed into iodate by different reactions depending on the degree of alkalinity.—E. **Toporescu**: The preparation of sodium bicarbonate. An experimental study of the reaction $NaCl + NH_4HCO_3 = NaHCO_3 + NH_4Cl$. The solubilities of the salts at 15° C. were taken first singly, then in pairs, and finally omitting one constituent only. The results are plotted on the square diagram due to M. H. le Chatelier (see above).—A. **Mailhe**: The catalytic decomposition of oleic acid. The vapour of oleic acid passed over copper-aluminium pellets contained in a copper tube maintained at 600°-650° C. gives a gas rich in olefines (10 per cent.) and an acid liquid. The hydrocarbons, freed from acids, commenced to distil at 40° C. (amylene) and contained about 50 per cent. of olefines. These were removed by hydrogenation over nickel at 180°-200° C., and hexane, heptane, benzine, toluene, metaxylene, and nonane were identified in the resulting hydrocarbon mixture.—A. **Schoep**: Stasite, a new mineral, dimorphous with dewindite. This was obtained from a chalcolite from Kasolo (Katanga, Belgian Congo), and analyses led to the formula $4PbO \cdot 8UO_3 \cdot 3P_2O_5 \cdot 12H_2O$, which is identical with the composition of dewindite, from which, however, the new mineral differs in its density, colour, and the form of its crystals. Its radioactivity is a little less than that of dewindite.—L. **Blaringhem**: Abnormal heredity of the colour of the embryos of a variety of pea, *Pisum sativum*. Certain strains of pea, like hordeum and flax, present striking irregularities in the transmission of discontinuous characters.—H. **Ricome**: The elongation of roots.—M. **Molliard**: A new acid fermentation produced by *Sterigmatocystis nigra*. The products can be made to vary by changing the constituents of the culture fluid. If the nitrogen is deficient *d*-glucosic acid is the main acid produced; if the phosphates are reduced, then citric and oxalic acids preponderate.—J. **Pellegrin**: A new blind fish from the fresh waters of western Africa. This belongs to a new genus named Typhlosynbranchus by the author. The character of the branchial apparatus places it in the family of Synbranchus.—A. **Lécaillon**: The characters of a male hybrid arising from the union of a male duck (*Dafila acuta*) and female wild duck (*Anas Boschas*).—P. **Cristol**: Zinc and cancer. The proportions of zinc in various forms of cancerous tumours have been estimated. The preliminary results show that the high proportion of zinc found in cancerous tumours is a function of the proliferation and the cellular and nuclear activity.—J. **Mawas**: The limphoid tissue of the middle intestine of the Myxinoides and its morphological signification.—C. **Bourguignon**: The treatment of contraction by electrical stimulation of the non-contracted muscles in the lesions of the pyramidal bundle and in the secondary contraction of peripheral facial paralysis. Evolution of the chronaxy in the course of the treatment.—C. **Levaditi** and A. N. **Martin**: The preventive and curative action in syphilis of the acetyl derivative of oxyaminophenylarsinic acid (sodium salt). This salt has been shown to be stable, very soluble, rich in arsenic and relatively slightly toxic, and has been used with effect in the cure by injection of experimental syphilis of the rabbit. The present experiments deal with administration by the mouth and not by injection, and it was proved that this salt would cure experimental syphilis rapidly in the rabbit and the ape. Two cases in man were successfully cured in the same way, and its preventive action was also shown on the human subject.

Diary of Societies.

FRIDAY, APRIL 28.

ZOOLOGICAL SOCIETY OF LONDON, at 4.—Anniversary Meeting.

ROYAL SOCIETY OF ARTS (Indian Section), at 4.30.—F. G. Royal-Dawson: The Need of an All-India Gauge Policy.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—T. Smith: The Position of Best Focus in the Presence of Spherical Aberration.—F. Twyman and J. Perry: The Determination of the Absolute Stress-variation of Refractive Index.—C. J. Smith: An Experimental Comparison of the Viscous Properties of (*a*) Carbon Dioxide and Nitrous Oxide, and (*b*) Nitrogen and Carbon Monoxide.—F. Twyman: Demonstration of the Optical Sonometer.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Museum Specimens illustrating the Forms of Inguinal Hernia.

ROYAL SOCIETY OF MEDICINE (Study of Disease in Children Section), at 5.—Sir Robert Jones: Presidential Address.

INSTITUTION OF AERONAUTICAL ENGINEERS (at Engineers' Club, Coventry Street, W.1), at 6.—Capt. Sayers: Some Unsettled Problems of Aeroplane Design.

INSTITUTE OF MARINE ENGINEERS, at 6.—Annual Meeting.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Prof. E. G. Coker and Dr. K. C. Chakko: An Account of some Experiments on the Action of Cutting Tools.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Capt. H. Whittaker: Some Notes on the Utilisation of Water Power.

ROYAL SOCIETY OF MEDICINE (Epidemiology Section), at 8.—Dr. F. Dittmar: Outbreaks of Enteric Fever associated with Carrier Cases.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. A. Harden: Vitamin Problems.

MONDAY, MAY 1.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—Annual Meeting.

INSTITUTE OF ACTUARIES, at 5.—E. H. Brown: The Valuation of Endowment Assurances by Select Tables.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. Shattock: Demonstration of Museum Specimens illustrating Sarcoma.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—Dr. C. V. Drysdale: The Testing of Small Electrical Plant.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Annual General Meeting.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—Miss M. MacFarlane: Prof. Alexander's Theory of Values.

ROYAL SOCIETY OF ARTS, at 8.—F. F. Renwick: Modern Aspects of Photography (1) (Cobb Lectures).

SOCIETY OF CHEMICAL INDUSTRY (at Chemical Society), at 8.

ROYAL SOCIETY OF MEDICINE (Tropical Diseases and Parasitology Section), at 8.30.—Annual General Meeting.

TUESDAY, MAY 2.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Sir Arthur Keith: Anthropological Problems of the British Empire. Series II.: Racial Problems of Africa (2).

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Prof. E. Mellanby: Some Common Defects of Diet and their Pathological Significance (Oliver Sharpey Lectures) (1).

INSTITUTION OF CIVIL ENGINEERS (Extra Meeting), at 6.—Sir John A. F. Aspinall: Some Post-War Problems of Transport (James Forrest Lecture).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.

RÖNTGEN SOCIETY (at Institution of Electrical Engineers), at 8.15.

WEDNESDAY, MAY 3.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—C. S. Franklin: Short Wave Directional Wireless.
SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8.—J. L. Lizius and N. Evers: Studies in the Titration of Acids and Bases.—C. Ainsworth Mitchell: Graphites and other Pencil Pigments.—Dr. J. C. Drummond: The Sulphuric Acid Reaction for Liver Oils and its Significance.—W. Singleton and H. Williams: Inadequacy of "A.R." Test for Alkalies in Calcium Carbonate.
ROYAL SOCIETY OF ARTS, at 8.—N. Heaton: The Production of Titanium Oxide, and its Use as a Paint Material.
ENTOMOLOGICAL SOCIETY OF LONDON, at 8.
INSTITUTE OF METALS (at Institution of Mechanical Engineers), at 8.—Sir Ernest Rutherford: The Relation of the Elements (May Lecture).

THURSDAY, MAY 4.

IRON AND STEEL INSTITUTE (at Institution of Civil Engineers), at 10.30 A.M.—F. Samuelson: Presidential Address.—F. Clements: British Siemens Furnace Practice.—D. E. Roberts: Notes on Blast Furnace Filling.—Prof. H. C. H. Carpenter and Miss C. F. Elam: Effect of Oxidising Gases at Low Pressures on Heated Iron.—C. R. Austin: Hydrogen Decarburisation of Carbon Steels, with Notes on Related Phenomena.—E. W. Ehn: Influence of Dissolved Oxides on Carburising and Hardening Qualities of Steel.
ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. E. H. Barton: A Syntonic Hypothesis of Colour Vision.
ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Dr. C. Shearer: The Heat Production and Oxidation Processes of the Echinoderm Egg during Fertilisation and Early Development.—Dr. H. Hartridge and R. A. Peters: Interfacial Tension and Hydrogen Ion Concentration.—W. Cramer, A. H. Drew, and J. C. Mottram: Blood-platelets and their Behaviour in "Vitamin A" Deficiency, and after "Radiation," and their Relation to Bacterial Infections.
ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Prof. E. Mellanby: Some Common Defects of Diet and their Pathological Significance (Oliver Sharpey Lectures) (2).
LINNEAN SOCIETY OF LONDON, at 5.—Prof. Lloyd Williams: The Life-history of Laminaria and Chorda.
INSTITUTION OF LOCOMOTIVE ENGINEERS (at Engineers' Club, Coventry Street, W.1), at 7.15.—J. A. Hookham: Comparison between Superheated and Non-superheated Tank Engines.
CHEMICAL SOCIETY, at 8.—I. E. Balaban and F. L. Pyman: Bromo-derivatives of Glyoxaline.—E. P. Perman: The Properties of Ammonium Nitrate. Part IV. The Reciprocal Salt-pair $NH_4NO_3 + NaCl \rightleftarrows NH_4Cl + NaNO_3$.—Prof. E. C. C. Baly and H. M. Duncan: The Reactivity of Ammonia.—Prof. E. C. C. Baly, Prof. I. M. Heilbron, and D. P. Hudson: Photocatalysis. Part II. The Photosynthesis of Nitrogen Compounds from Nitrates and Carbon Dioxide.
CIVIC EDUCATION LEAGUE (at Belgravia Hotel, Grosvenor Gardens, S.W.1), at 8.15.—W. de la Mare: Character.

FRIDAY, MAY 5.

IRON AND STEEL INSTITUTE (at Institution of Civil Engineers), at 10.30 A.M.—D. Selby-Bigge: Recent Developments in Power Production.—A. Westgren and G. Phragmen: X-ray Studies on the Crystal Structure of Steel.—N. T. Belaiew: The Inner Structure of the Pearlite Grain.—J. H. Whiteley: Formation of Globular Pearlite.—A. F. Hallimond: Delayed Crystallisation in the Carbon Steels: the Formation of Pearlite, Troostite, and Martensite.—K. Honda: The Constitutional Diagram of the Iron-Carbon System based on Recent Investigations.—K. Honda and T. Kikuta: The Stepped A1 Transformation in Carbon Steel during Rapid Cooling.—N. Yamada: The Heat of Transformation of Austenite to Martensite, and of Martensite to Pearlite.
ROYAL SOCIETY OF ARTS (Dominions and Colonies and Indian Sections), at 4.30.—Prof. W. H. Eccles: Imperial Wireless Communication.
ROYAL ASTRONOMICAL SOCIETY (Geophysical Discussion), at 5.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Demonstration of Muséum Specimens illustrating Umbilical and Diaphragmatic Hernia.
INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section), at 7.—R. P. Howgrave-Graham: Electrically Oscillatory Discharges.
INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7.—Failures.
ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. M. Grabham: Biological Studies in Madeira.

SATURDAY, MAY 6.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. D. H. MacGregor: Industrial Relationships (2). The Problem of Structure.

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, APRIL 28.

BEDFORD COLLEGE, at 5.15.—Prof. E. Claparède: L'Intelligence et la Volonté (1). (In French.)
KING'S COLLEGE, at 5.50.—Dr. J. Hjort: Biological Aspects of Oceanography (1).

MONDAY, MAY 1.

BEDFORD COLLEGE, at 5.15.—Prof. E. Claparède: L'Intelligence et la Volonté (2). (In French.)
KING'S COLLEGE, at 5.30.—Dr. J. Hjort: Biological Aspects of Oceanography (2).

TUESDAY, MAY 2.

UNIVERSITY COLLEGE, at 5.—Sir Arthur Shipley: Insects and Disease (1).
BEDFORD COLLEGE, at 5.15.—Prof. E. Claparède: L'Intelligence et la Volonté (3). (In French.)
KING'S COLLEGE, at 5.30.—Dr. J. Hjort: Biological Aspects of Oceanography (3).—Prof. H. Wildon Carr: The Principle and Method of Hegel (1). The Real and the Rational.

WEDNESDAY, MAY 3.

ROYAL SOCIETY OF MEDICINE, at 5.—Prof. C. Winkler: The Human Neo-Cerebellum.
UNIVERSITY COLLEGE, at 5.15.—Dr. D. H. Scott: The Early History of the Land Flora (2).

THURSDAY, MAY 4.

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 5.—Sir Archibald E. Garrod: More Inborn Errors of Metabolism.
ROYAL SOCIETY OF ARTS, at 5.15.—Sir Lawrence Weaver: Rural Re-Settlement and its Relation to Public Health (1) (Chadwick Lecture).

FRIDAY, MAY 5.

UNIVERSITY COLLEGE, at 5.—Prof. T. Borenius: The Re-discovery of the Primitives (Admission by Invitation only);—at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (1).
KING'S COLLEGE, at 5.30.—Dr. J. Hjort: Biological Aspects of Oceanography (4).—R. F. Young: The University of Prague.

Government Scientific Services.

IN a presidential address to the Washington Academy of Sciences[1] Mr. Alfred H. Brooks deals with the "Scientist in the Federal Service," and incidentally provokes comparison of Government scientific services in Britain and the States. The field to be covered, as he remarks, is continental in dimensions, and the needs of upwards of one hundred millions of people have to be met. So vast a proposition is beyond the powers of private enterprise and demands the systematised efforts of national bureaus. Washington, as the city of Government, formed the natural centre of Government research, and only during the last two decades became the home of other scientific institutions. In Paris, Berlin and London, science was fostered by old universities and learned societies, and it was only in researches for which co-operation on a large scale, and the maintenance of a permanent staff, were necessary, that the Government lent its aid.

The Federal scientific worker, we are told, giving his whole time to science, may tend to lose enthusiasm, and Mr. Brooks expresses a regret, with which we fully sympathise, that the non-professional man of science, with his enthusiasm and power to vivify science, is almost unknown in Washington and would fail to find there a congenial atmosphere. But in his fear that organised science leaves no place for the amateur and that competition with highly organised corps of professionals is impossible, surely he is unduly pessimistic. In Britain, at any rate, the amateur not infrequently leads the way and indicates the channels along which professional effort should be directed.

The Federal scientific service commenced about 1816. Now there are about forty institutions and upwards of 1500 investigators. At first the obtaining of funds depended largely upon the personality of the bureau chief. Pay was scanty, regulations were few, and appointments were made too largely under political influences. As practical applications of science increased, the bureaus were enlarged, and business methods were introduced, especially after 1906, as a result of the recommendations of the Keep Commission. Still more important was the realisation by the higher Government officials of the value of science in national economic problems. The demand for men began to exceed the supply, and whereas a bare living and a God-given love for his subject had been the scientific worker's only motives, the service became a profession for which the Universities graduated scores of highly trained specialists.

The tendency of a Federal service to collect facts without providing adequate interpretation, is inevitable. Organisation leads to uniformity, and, though a good

[1] *Journ. Washington Academy of Sciences*, vol. 12 (1922), pp. 73-115.

administrator may encourage individual effort in constructive thought, more consolation is found in the fact that the rare scientific genius cannot be suppressed, though there may be some danger of his applying his originality to financial and routine matters. Familiar indeed are the difficulties which scientific workers find in complying with the regulations controlling their expenditure, or accepting the limitations which a Treasury finds, or may think, necessary to place upon it. Regulations and limitations are regarded as personal insults, for the purpose only of hampering research.

The direction of a group of strongly individualistic investigators, including, it may be, a master mind, and almost certainly several hewers of wood and drawers of water, is no light task. Originality of thought has to be encouraged, but unity of purpose must be maintained in order to achieve the results demanded under the grant. The delinquents in such a group are usually unconscious of any delinquency, as for example the dilettante who flits from one problem to another and believes that he fulfils all obligations if he merely remains on the pay-roll; the brilliant mind that is so undisciplined that it cannot be made to formulate conclusions; or the hard-working procrastinator who dare not put forward his conclusions for fear of omitting some detail. Less deserving of sympathy are the pests who are as quick as a hair-trigger in publishing, and rush into print where more experienced men fear to tread, or the self-selected mouthpiece, who, unwilling to hide his light under a bushel, constitutes himself the agency by which science reaches the average man, and is too often taken at his own valuation. The "professional prominent scientist," another familiar type, at one time formed the popular authority in Washington. His dictum on any new problem was final, but he was more highly reputed by the public than by his colleagues.

A criticism passed on all men of science, not only by Mr. Brooks but also by literary men in Great Britain, relates to the form in which science is presented. The greatest need of the average American, and we may add of the British man of science, is to write clear English. He conveys his message to the people in language they cannot understand, and often he and his colleagues fail to understand one another. The development of such curiously similar types on the two sides of the Atlantic is interesting.

On the outbreak of war the Federal service proved its true worth. The bureaus formed the backbone of war service, for they were immediately available as storehouses of scientific facts and their great corps were quickly turned on to war problems. One result was to reveal the high commercial value of science, with the consequence that the ranks of the Federal service have been most seriously depleted. The best-trained men are now tempted away by the financial prospects of a commercial career, and the second choice only is left to the Government. It is suggested that the change may be due to the lowering of the ideals of the student, for the professor who is compelled to eke out a small salary by taking commercial work or writing text-books for profit, has not the same influence as a "revered master" in research. Without disparaging the high ideal attributed to the student, one is tempted to think that the possibilities of far higher emoluments in commercial service than could be justified in a Government bureau, are the principal inducement.

Pay, however, is not everything. Mr. Brooks reminds us that the young investigator who has obtained a post in the Government service, finds himself a member of a corps of well-trained enthusiastic professional men, whose actions earnestly express public duty and self-sacrifice. He will enjoy among them and in the non-professional societies congenial scientific companionship, and he will realise that the mere mass of such an army of investigators, whose ideals are not less lofty because they include the welfare of mankind, give an inspiration not excelled elsewhere.

The Design of Electric Power Stations.

Power House Design. By Sir J. F. C. Snell. (Longmans' Electrical Engineering Series.) Second edition. Pp. xi + 535. (London: Longmans, Green and Co., 1921.) 42*s.* net.

THE second edition of this important work will be welcomed by all engineers who are interested in power-station design. The author is the chairman of the Electricity Commissioners; he has been both a distributing and a consulting engineer, and has therefore studied the problem from all points of view. The book is a storehouse of facts which will be of great value to the designer. The general principles which should be followed are laid down and illustrated by clear descriptions of many modern power stations. It is interesting to note that these stations are of very varied design. This is doubtless due partly to the individual experience of the designers, but it also bears out the author's contention that every case must be considered on its own merits, and so the solution applicable in one case may be unsuitable in another. The apparatus inside a power station should be standardised as much as possible, but at the present time it would be inadvisable to attempt to standardise the station itself.

The modern fashion is to concentrate generating

plant in large stations. This necessitates having a large supply of circulating water in the neighbourhood and it follows that capital stations are not necessarily situated near a pit's mouth. The most economical engines for driving dynamos are steam-turbines, provided they are worked at a very high vacuum, and in order to secure this we must have a supply of cold water equal to seventy times that required by the boilers. It is this consideration that rules out practically all the colliery sites in this country.

The author thinks that there should be at least two main generating stations to supply a large district. In addition he says that it generally would be found economical to generate part of the load at the points where the demand is greatest. It seems to us that the author does not lay sufficient stress on the fact that the cost of the network of cables required in a large distributing scheme may be 70 or 80 per cent. of the total cost of the undertaking. The main factor in determining the sites, therefore, will be the cost of the cables required. The cost of fuel transport and of the arrangements for circulating water may not vary much for different sites, but in general for a given supply the cost of the requisite cables will vary largely with the position of the power station. For commercial success it is very important that the capital cost of the cables should be as small as possible, and this can only be secured by a close study of the nature of the load required for industrial, domestic, and transport purposes, and then choosing the sites so that the cost of the cables is as small as possible. If the undertaking is to be a success, it is also necessary that the power-houses be capable of continual extension, so that the power available need never be much in excess of the demand. In the early days of the industry many of the stations built were much too large for the demand, and consequently years had to pass before they could pay dividends. It was difficult, therefore, to finance new schemes.

The following interesting comparison is made between the relative value of steam-engine and gas-engine plant. A boiler can easily evaporate 7·5 lb. of steam per lb. of coal consumed; a ton of coal will therefore yield 16,800 lb. of steam. A modern steam-turbine requires 8·2 lb. of steam per brake horse power hour developed. Hence a ton of coal will produce 2049 B.H.P. hours. With a gas producer operating on an average at a thermal efficiency of 75 per cent., a ton of coal of the same calorific value will yield power gas capable of producing 20,160,000 British thermal units. We may assume that on an average a modern gas-engine requires 9500 B.Th.U. per B.H.P. hour, and hence a ton of coal utilised in this way will produce 2122 B.H.P. hours. There is not much difference, therefore, in the amount of the mechanical energy obtained from the coal by the two methods.

It is pointed out that in certain cases an economy in fuel consumption can be obtained by using both steam and gas plant in the same station. The gas plant is almost immediately available, and so can be used to cope with any sudden temporary increases in the load, with consequent economies.

It has often been urged that it would be more economical to extract the potential by-products from the coal first of all and then utilise the resulting fuel products for power purposes. The author makes a careful examination of this procedure. He points out that serious thermal losses are involved in treating coal for by-product recovery and converting into coke or power gas or both. These losses range from 25 to 50 per cent. In the case of a power-house equipped with ammonia recovery producers for gasifying the whole of the coal, the total coal consumption would be from 70 to 80 per cent. greater than that of a corresponding coal-fired station. Considering it from the commercial point of view, he concludes that the prospects of obtaining through the medium of by-product recovery processes bulk supplies of electrical energy at a lower cost than coal firing are practically negligible.

Owing to the increasing attention devoted to the question of fuel conservation during the past twenty years, important developments in the utilisation of thermal products, which were formerly wasted on an enormous scale, have taken place. In particular, the surplus fuel gases produced at iron and steel works have been successfully utilised; for instance, at the important coke-oven works of Messrs. Pease and Partners, Durham, the waste heat is transformed into electrical energy by the supply company, and is "pumped" into the high-tension transmission mains for utilisation throughout the district.

The concluding chapter discusses hydro-electric power-houses, and important stations in America, Mexico, and Sweden are described. The attraction of cheap electric power has caused flourishing towns to spring up in the neighbourhood of some of the American waterfalls, but there are few cases where the hydro-electric power generated is transmitted to a considerable distance.

The author assumes that the reader is an engineer. The general reader, therefore, will occasionally have difficulty in understanding his nomenclature. The importance, for instance, of the load-factor of a station is emphasised, but even the engineer would appreciate being reminded that the load-factor is the ratio of the average load to the maximum possible load. The higher this factor, the more promising the com-

mercial outlook of the station. Later on the notion of the diversity-factor is introduced, defined as the ratio of the sum of the maximum loads on the separate substations to the maximum load at the power-house. It is generally assumed that the higher the diversity-factor, the load-factor remaining the same, the better it is from the commercial point of view. It seems to the writer that these definitions should be examined from a rigorous mathematical point of view to find how far their numerical values can be considered as trustworthy guides of the commercial practicability of a projected scheme.

A "silo" is generally considered to be a pit or cave for storing fodder in the green state. Engineers apparently call a coal-store a "silo," and that at the Greenwich power-house has a capacity of 2000 tons. The coal is fed from the bunkers, into which the silo is divided, into gravity bucket conveyors, which carry it to the overhead bunkers feeding the furnaces. The weight of the coal is checked on weigh-bridges with five-foot dials. It is stated that with a load of 5 tons the maximum inaccuracy is only about 3 lb.!

A. RUSSELL.

Witch-Craft in Western Europe.

The Witch-Cult in Western Europe: A Study in Anthropology. By M. A. Murray. Pp. 303. (Oxford: At the Clarendon Press, 1921.) 16*s.* net.

IN her study of witchcraft in Western Europe Miss Murray has endeavoured to show, first, that the witch-cult was a definite organised religion, and secondly, that it is possible to deduce from the records the character of its ritual. The problem which Miss Murray has set herself is entirely new and has not hitherto been considered, much less attacked.

As regards the evidence upon which Miss Murray's investigations are based, her aim has been to arrive at an impartial statement by quoting the *ipsissima verba* of the witches in their confessions and at their trials as recorded by contemporary chroniclers, all comments of those who compiled the records being omitted. Early accounts of witchcraft, as she points out, are apt to be vitiated by too great credulity or an excess of scepticism.

Exception is not infrequently taken to the evidence of the witches themselves on the ground that it was elicited under torture, but Miss Murray meets this objection by pointing out that in the English trials and in many of the Scottish trials legal torture was not employed. It is true that she is concerned principally with witchcraft in this country and deals with the French evidence only for purposes of elucidation and amplification; much of the French evidence was the result of torture, and even in this country in some of the most important cases torture was employed. In the case of the North Berwick witches, who were accused of a conspiracy against James VI. in which Bothwell was implicated, two were subjected to the ordeal of having their nails pulled out with pincers, pins were stuck into the quick, and they were tortured with the boot. It is to be noted, however, that the confessions, whether elicited under torture or without it, display a remarkable uniformity in detail, although drawn from a wide area and spread over a considerable period of time. This lends strong support to the view that the evidence may be accepted as it stands.

Taking the evidence at its face value, Miss Murray has arrived at the conclusion that the witch-cult was a definite organised religion and, as such, was a survival of the primitive religion of Western Europe. It represents, she holds, the religion of a pre-agricultural people who celebrated their religious festivals in accordance with a pre-solstitial calendar. She argues, reasonably enough, that the wholesale conversions to Christianity in the early days of tribes and peoples were merely superficial and that the bulk of the people continued to follow their old beliefs and to practise their traditional ritual, more or less in secret. If it be conceded that the witches in their accounts of what took place at the Sabbaths were describing, not furtive assemblies for malicious evil practices and unlimited debauchery, but gatherings for performing the rites of an organised religion, their evidence takes on an entirely new significance. Taking this point of view Miss Murray is able to deduce from it the character of the god they worshipped, the nature of the rites, and the organisation by which the religion was carried on.

The god, who was confused with the devil by Christians, was regarded by his worshippers as incarnate in man, woman, or animal. The animal form varied, being sometimes a bull, sometimes a dog, a cat, a horse, or a sheep. The goat, common in France, does not occur in this country. Further investigation of this point might throw light on the early history and distribution of the cult. The god incarnate acted as the leader of the association in which there was an inner circle or council, the "coven," consisting apparently of thirteen individuals. Miss Murray is of the opinion that in certain instances it is possible to identify these leaders, and cites, among others, Bothwell, Joan of Arc, and her companion in arms, Gilles de Rais, the French "Bluebeard." Her suggestion that the god was sacrificed at stated intervals would account for certain peculiar features in the trials, such as, possibly, the line taken by Joan of Arc under examination, and the

unsolicited confession of Major Weir, who was burned as a witch at Edinburgh in 1670. The evidence on this point would not be strong in itself, if it were not fully in keeping with Miss Murray's view of the witch-ritual. As is well known the central features of the Sabbath were a feast and sexual licence. This suggests inevitably that it was a fertility rite of the type familiar to anthropologists. It was only at a later date, and in the first instance by popular perversion that the function of the witch became the blasting of crops and herds as set forth in the famous Bull of Innocent VIII.

Many other topics are discussed in this important study which are of the greatest interest to anthropologists, and it bristles with points which call for further consideration did space allow. It has, however, one aspect to which reference must be made, and that is its bearing upon mediæval history. From this point of view it is a book which no historian or student can afford to neglect. The position of the Church and its relation to witchcraft before the beginning of the fifteenth century must be reconsidered first in the light of Miss Murray's conclusions and, secondly, with reference to the numerical strength the cult could command as an organisation—a point upon which Miss Murray does not touch.

The Riddle of Bird Migration.

Die Rätzel des Vogelzuges. Ihre Lösung auf experimentellem Wege durch Aeronautik, Aviatik und Vogelberingung. Von F. von Lucanus. Pp. viii + 226. (Langensalza: H. Beyer und Söhne (Beyer und Mann), 1922.) 30 marks.

THE migration of birds remains one of the most tangled problems, as it is one of the greatest marvels of the zoologist's world. In the old days known facts were few and hypotheses were correspondingly simple (and as a rule erroneous), but with multiplicity of data, theories, guesses and suggestions have so increased in number and complexity that they form in themselves a new problem for the seeker after truth. In the matter of precision of data the present generation holds a great advantage over its predecessors.

The institution of bird-ringing in Denmark by Mortensen in 1899, and its subsequent development in Germany by Thienemann and others, and in this country by the University of Aberdeen and Mr. Witherby, raised hopes of an early solution of many difficulties; while the development of air-craft and of their use in bird-watching, in which von Lucanus himself was a pioneer, has led to information which appeared once to be beyond man's grasp.

In the light of the results of these new methods, von Lucanus restates the problems of the origin and causes of migration, of its direction, height and speed, of its meteorological relations, and, most subtle of all, of the pathfinding of the birds, and re-examines the solutions which have been suggested. It may be said at once that there are here many new facts, and that in many respects the work of the former generation of observers has been superseded; but with it all, the reader is left with the feeling that while precision has been gained in problems of observation, the great problems of interpretation remain still beyond ken. Time after time the author is driven back for explanation upon an incomprehensible "migratory instinct" or "impulse" (Zugtrieb). Thus, having rejected, on account of their inadequacy as imminent causes of autumn migration, the fall of temperature, the shortening of the day, the lack of food, the changed atmospheric conditions due to the passing of the summer solstice, he concludes, "a bird departs as soon as the time for its departure has come and the migratory impulse has been awakened, without requiring any particular external stimulus.' Or again, having found tradition, warmer zones, anticyclonic conditions, wind guidance, a supposed magnetic sense, power of vision, each and all insufficient to account for the orientation of a bird's migratory flights, he says, "on its journey a bird requires no particular guidance, but follows an instinct which decides the direction automatically."

Von Lucanus has long been recognised as the champion of migration at comparatively low levels in the air, as against the idea of high-level migration which Gätke made popular. Many observations by airmen have been added to his early balloon observations, and he still regards the general height of migration to be under 400 metres, and flight at 1000 metres or over to be exceptional. Many records support his view, but conflicting evidence involves us in difficulties, for the author makes no mention of the observations of such of our airmen as Capt. Collingwood Ingram, who saw a flock of five hundred geese or ducks at about 11,500 feet, cranes (possibly) at 15,000 feet, birds resembling linnets at 10,000 feet, sandpipers at 12,000 feet, and so on. (*Ibis*, 1919, p. 321-5.)

The riddle of migration is not solved, but this volume, rich in observations and analyses, gives an excellent synopsis of the present state of knowledge, and points the way for future research. We may express the hope that the German bird-watching stations, disorganised owing to post-war conditions in Germany, may soon be able to resume their activities and add to the vast contributions they have already made to a fascinating study.

J. Ritchie.

Modern Chemistry.

Traité de Chimie Générale. Par Prof. W. Nernst. 2e édition française, complètement refondue d'après la 10e édition allemande par Prof. A. Corvisy. Première Partie: *Propriétés Générales des Corps—Atome et Molécule.* Pp. viii+620. (Paris: J. Hermann, 1922.) 30 francs net.

PROF. NERNST'S monumental treatise on general chemistry is so well known in this country and in America that no commendation of it is needed. It is a standard work in Germany, where it has already gone through numerous editions. In its French dress it has established a position in other parts of Europe and in Latin America. The volume under review—a large octavo of more than 600 pages—is the first part of the second French edition; it has been thoroughly revised in conformity with the latest German edition. It deals with the general properties of matter and with atomic and molecular theories in the light of contemporary knowledge. In effect it is a treatise on the application of the fundamental principles of modern physics to chemistry, with due regard to inquiries wherever the study of chemical physics is actively pursued. Indeed, the wealth of bibliographical reference is one of the most commendable features of the work. This, of course, is as it should be. Science knows no national boundaries. This was not always so recognised in Germany. In times not so very remote it was not unusual to notice a tendency to make the world believe that the study and development of physical science, and particularly chemistry and physics, had become almost the exclusive function and prerogative of German professors. Instances were not unknown of actual appropriation of other men's work or of the wilful suppression of all mention of their labours. No such charge could possibly be brought against the author of this work. He apparently keeps his eyes open to all sources of knowledge and welcomes evidence from any quarter.

Although the general plan of the work is unchanged, the alterations and additions in the present French edition are very considerable. Many of the paragraphs have been greatly modified, and in some cases wholly rewritten; others have been added; some of the less important have been shortened and even discarded, so as to keep the book within bounds. Theoretical conceptions and new developments which found no mention in the first edition, such as the quantum theory, the constitution of the atom, the new thermodynamical theorem, the theory of relativity, atomic numbers, equations of state, the molecular theory of the solid state, the frequency of atomic vibrations, the elucidation of crystal structure by X-rays, radioactivity, isotopism, etc., now find their appropriate place and are dealt with at due length. The book is eminently readable, and the mathematical treatment in no wise deterrent. Prof. Nernst's excellence as an expositor has in no sense suffered by the clarity and precision of Prof. Corvisy's rendering. The book is remarkably free from typographical errors, although, as might be expected in a volume of its size, a few mistakes occur here and there. It will be news to many readers that a Lord Rayleigh developed a certain formula relating to gaseous mixtures so far back as 1587.

Text-books of Elementary Mathematics.

(1) PROF. OSGOOD'S "Elementary Calculus" supplies a need—the need of the young mathematician for a sound introduction to the differ-

ential calculus. The treatment is almost without blemish and is so simple and clear that the beginner should have no serious difficulty. Chaps. 1-4 introduce only algebraic functions; chaps. 5-8 are concerned with trigonometric and exponential functions and the corresponding inverse functions. The treatment of infinitesimals and differentials in chap. 5 is specially to be commended. The author has one or two hobby-horses. One that he ought not to have ridden here is the denial of the existence of "infinity." He says (p. 27): "We should not read 'Z approaches infinity,' . . . but 'Z becomes infinite'; . . . the statement sometimes made that 'Z becomes greater than any assignable quantity' is absurd. There is no quantity greater than any assignable quantity." This last remark contains a certain misunderstanding, and, in any case, such subtleties are not suited to beginners. Among minor points it is curious to note that there is no definition of a limit in the book. Some proof, or at least a reference, should be given for the proposition quoted on p. 113: "A convex curved line is less than a convex broken line which envelops it and has the same extremities."

(2) It is a pity that authors who do not "make reference to difficulties which seldom arise in the minds of elementary students" generally manage to make their subject so uninteresting. We do not ask for proofs. Mr. Sydney Jones effectually suppresses such an unreasonable desire by putting the word "proofs" in inverted commas in his preface. But could we not have a little colour? Let us take MacLaurin's theorem as a sample (p. 158). Mr. Jones says: "Assuming that a function $f(x)$ can be expanded in positive integral ascending powers of x . . . .

$$f(x) \equiv A_0 + A_1x + A_2x^2/1.2 + \ . \ . \ . \ ,$$

to determine the coefficients A_0, A_1, A_2, . . ." He then differentiates the series and determines the coefficients, as if this were a most ordinary and most dull proceeding. His pupils no doubt wonder vaguely, learn their lesson by rote, and pass on. If he would only pause to tell them what a wonderful theorem this is, or point out how great are the assumptions he is making, it would be well worth the space. Judging the book from the author's own point of view, there is little to find fault with in it. But he should not call a differential coefficient a "differential" (p. 18, etc.).

(3) This misuse of the word "differential" is a bad habit that appears to be gaining ground. The authors of "A First Course in the Calculus" are also addicted to it (preface and p. 215). Their text-book is mainly manipulative; it contains the usual treatment of the infinitesimal calculus, and concludes with a chapter on differential equations. The proof, depending on the area of a circular sector, for the limit of sin θ/θ (p. 181), is open to the objection that students are generally taught to use the limit in question for finding this area. It is not necessary to use a formula for an area at all (see, for example, Levett and Davison's "Plane Trigonometry," p. 82). Many mathematicians would be pained by the author's statement on p. 343: "If we proceed indefinitely, taking only a fractional part of a given object, it is perfectly plain that the fractional portion will soon be very small indeed." There is no doubt that an intelligent person can convince himself that the limit of x^n is zero, if x is less than unity, but a more exacting logician demands a proof of the proposition. The authors hope that "the student will have nothing to unlearn if he afterwards . . . proceeds to a rigorous course of modern analysis." But it would be a pity if he learnt to regard analysis as the proving of the "perfectly plain."

(4) Mr. Gheury de Bray calls his book a "little brother" of "Calculus Made Easy." We do not know whether the late Prof. S. P. Thompson would have been pleased with this facetious little relative. The only portion of the work that we can unreservedly recommend is a long preliminary quotation from Henri Fabre (pp. 1-12). There follow part 1 on indices, binomial series, etc., and part 2 on the exponential series, the equiangular spiral, the hyperbola (because its area is a logarithmic function), the catenary, the parabola (because it resembles a catenary), the probability curve, and "exponential analysis." The method consists in "talking round" the subject; something may be said for it, but it requires skilful handling, and in this author's hands it is often long-winded and obscure. The unwary should be warned that the method, which is stated on p. 55, is not "mathematical induction," but a kind of sampling; the statement on p. 147 that the centroid of a catenary arc is its middle point is, of course, incorrect. The last chapter is interesting, but too difficult for any one who would care to read the rest of the book. In sum the author had an excellent idea, which he has not quite managed to realise.

(5) "Mathematics for Technical Students" is designed for the first two years' work following on an elementary school course. The treatment is apt to be rather too formal in places—Mr. Forrest teaches algebra in the old style like a game of patience with x's and y's for playing cards, and only hints that algebra has something to do with the workaday world after his pupil has learnt to play the game. The treatment is, of course, still quite defensible, but it is now generally thought better to reverse this order

with technical students, who are only too apt to regard mathematics as a game instead of an essential part of their business. The book is, for the rest, well proportioned and quite suitable for its purpose.

(6) The subject known as "Elementary Algebra" has been so metamorphosed in the past ten or twenty years that its name ought to be changed. Graphs, differentiation, integration, and nomography are not algebra as understood by Salmon, Chrystal, or Weber. A little trigonometry and as much geometry as is required should be added and the whole called elementary mathematics. The breaking down of the watertight compartments into which school mathematics used to be divided is a development in the right direction.

The scheme of this book is interesting. The bookwork is only given in outline in the text or hinted at in the introduction. It remains for the teacher to fill in this framework according to his own lights. And then the text-book gives him examples that are both numerous and apposite. The scheme has much to recommend it, and will be welcomed by teachers who are accustomed to do their work thoroughly. The authors need not apologise for introducing a chapter on nomography, although this chapter will be found difficult without a much fuller treatment.

(7) It is a melancholy fact that examinations dominate and thereby spoil much of the education that they are intended to test and encourage. A considerable part of the education in this country has no higher purpose than the passing of a public examination at some future date. Mr. Durell, who is capable of much better things, says quite frankly that he has compiled a cram book, and we can recommend it for that purpose. The range is roughly that of the Cambridge schedule.

(8) The syllabuses for the Army entrance examinations and those conducted by the Oxford and Cambridge Joint Board have been assimilated, in the hope that Army classes at public schools may thereby be discontinued. This is a little unfortunate for Mr. Fawdry, whose "Co-ordinate Geometry" is written for Army candidates. But the book should prove quite suitable for the general classes into which the Army classes may be merged. Mr. Fawdry has the humanity to insert one or two historical notes (pp. 29 and 75). They are slight, but it is wonderful how much interest they add to the reading. We should like to see more of them.

(9) One of the difficulties of the teacher of modern elementary geometry is the devising of life-like examples. He will solve this difficulty if he gets Mr. Scott's text-book on practical geometry. The text-book is meant for young draughtsmen, and is full of such things as draughtsmen have to draw. The only general criticism we would make is that, while Mr. Scott gives clear instructions, he never justifies them, and we cannot believe that rule of thumb is a good rule even for draughtsmen. Chap. 8, about which the author is a little apologetic, is rather out of place. It contains some methods of constructing a "true length," when plan and elevation are given. The chapter is good in itself, but it stands at a different level from the rest of the book. The subject should be either left out or treated more fully. Standing alone, it will not be understood by the majority of readers.

H. B. H.

Studies in Symbiosis.[1]

Tier und Pflanze in intrazellularer Symbiose. By Prof. P. Buchner. Pp. xi + 462 + Tafel 2. (Berlin: Gebrüder Borntraeger, 1921.) 114 mk.

THE third section of Dr. Buchner's book deals with the highly controversial thesis that symbiotic bacteria are the cause of luminosity in many insects and marine animals. In this discussion, the author's critical faculty is at fault. He does not set out clearly the opposing lines of evidence nor does he do full justice to the work of Dubois, the protagonist of the "enzyme-theory" of animal luminosity.

Briefly, the issue is between the enzyme and the bacterial modes of light production. According to Dubois and Newton Harvey (whose work was reviewed in NATURE, October 6, p. 174), luminous animals contain two substances, one of which, when oxidised in the presence of the other, gives rise to light of an extremely "efficient" kind. The firefly's light is the standard—the most efficient light known, so far as the amount of light in relation to the expenditure of energy is concerned. One of these substances is a heat-stable, dialysable, oxidisable light producer, the other is not heat-stable, is non-dialysable, and is apparently a proteid. These substances are obtained by "dissolving" whole animals or their phosphorescent mucus in water or alcohol and precipitating with ammonium sulphate. No attempts appear to have been made to test the solutions for the presence of bacteria. An aqueous emulsion boiled in 20 per cent. hydrochloric acid for three hours retains the power of producing light when added to a cold-water emulsion. In the former the heat-stable "luciferin" has been separated from the unstable catalyst "luciferase," while both are present in the cold-water extract. The presence of the activator is necessary for light

[1] Continued from p. 539.

production which in that case accompanies the rapid oxidation of luciferin; otherwise the process occurs without the evolution of light. The cold-water extract glows for a time until its luciferin is completely oxidised, and it may be made reluminescent by adding some of the hot-water extract.

The bacterial theory of animal light, though possibly consistent with the enzymic one, is based on entirely different data. In its modern form, as an explanation of the phosphorescence of fireflies, glow-worms, and such marine animals as Pyrosoma and certain cuttle-fish, it is due to Italian zoologists, and especially to the work of Pierantoni. Dr. Buchner is a convert to this view and is a worker in this field. He gives a very interesting account of the evidence, which is of a biological, and not, as in the case of the enzyme school, of a chemical character. According to these observations, the luminous organs of cephalopods, be they never so complicated, are essentially cultures of bacteria in media suitable for their nutrition, and in situations favourable for obtaining oxygen.

In the common Sepia, for example, the organ (hitherto called the accessory nidamental gland and regarded as part of the egg-producing mechanism) consists of a modified part of the mantle within which different kinds of bacteria occur. Some are luminous, others are not. They also occur in the egg membrane before development, and Pierantoni describes the infection of the embryo by bacteria derived from those of the egg capsule. In a similar manner he explains the relationship between the luminosity of the egg of the glow-worm and that of the larva and adult beetle. The cells of the luminous organ of Pyrosoma contain structures that are also apparently symbiotic organisms. Noctiluca, however, has not yet been examined from this point of view.

The difficulty that many will feel in regard to this or the rival solution of an admittedly complex problem is the incompleteness of the explanation hitherto given of flash and occultation and of the apparent transmission of a mechanical stimulus from one part of a luminous animal (as in Pyrosoma) to another, lighting the "lamps" as it travels along. The solution seems to lie in the phases and disturbances not only of respiration, but of other controlling factors leading to continuous or alternating evolution of light.

Dr. Buchner has performed a signal service by collating much of what is known of intracellular symbiosis in animals, and his book is one that is most suggestive for further experiment and observation. It indicates the fruitfulness of border-line investigation, and should be widely known amongst biologists to whatever section of organic science they may belong.

Our Bookshelf.

Industrial and Power Alcohol. By Dr. R. C. Farmer. (Pitman's Technical Primer Series.) Pp. x+110. (London: Sir Isaac Pitman and Sons, Ltd., 1921.) 2s. 6d. net.

THE author has certainly contrived to include a very large amount of information regarding alcohol in this little book, which contains clear descriptions of the properties of the alcohols and the methods of production. There are interesting chapters on the technical applications and the use of alcohol for the development of power. By no means the least informative part of the book is the numerous references to government regulations and restrictions. Thus, after a statement of some of these restrictions, we read on page 31:—"Plant is stereotyped, and there is no encouragement to introduce improvements in method or in apparatus. Transport by tank is forbidden, and no distillery is permitted to be more than a quarter of a mile from a market town, whereas it would frequently be better to situate the distillery near to the raw materials." We can commend this book to any who are interested in the development of alcohol as a fuel.

Les Combustibles liquides et leurs Applications. Par le Syndicat d'Applications Industrielles des Combustibles liquides. Pp. iii+621. (Paris: Gauthier-Villars et Cie, 1921.)

ONE may liken this volume to the many similar pocket-book issues extant in this country as compendious guides to the various branches of applied science. It serves a double purpose as an epitome of petroleum technology and as a standard work of reference for immediate requirements in the field, refinery, and office, and although written essentially for the use of the French industries concerned with inflammable liquids, it deserves a much wider sphere of utility. This type of publication, though frequently condemned as inimical to the best interests of scientific work and commercial production, commands a degree of popularity for which it is not, perhaps, difficult to account.

H. B. MILNER.

The Development of Institutions under Irrigation; With Special Reference to Early Utah Conditions. By Prof. G. Thomas. (The Rural Science Series.) xi+293. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1920.) 16s. net.

PROF. THOMAS aims at tracing the evolution of water legislation in Utah from 1847, when the Mormon pioneers founded Salt Lake City, to the present time. He shows how the Mormons, if not the first people in America to practise irrigation, were certainly the first to establish it on an extensive scale, the whole of their civilisation practically resting on this type of agriculture. They showed the way to reclaim vast areas of arid land and on their pioneer attempts have been based the methods utilised in other parts of the United States. He also traces the influence of this type of agriculture on the plan and design of the cities of Utah. The book would have been improved by the addition of a map.

Letters to the Editor.

The Buoyancy of the Sun-fish.

ABOUT the end of August numbers of sun-fish (*Orthagoriscus mola*) make their appearance off the north coast of Ireland floating passively on the surface of the sea. The positive buoyancy, while not so great as to prevent the fish from submerging when attacked, constitutes a constant upward drag which brings it back to the surface as soon as it stops swimming. So far as we know, the bodies of all other fish have a specific gravity greater than that of sea-water, and the swim-bladder, where it exists, contains the necessary amount of gas to compensate for this and bring the body of the fish to neutral buoyancy.

The sun-fish has no swim-bladder, and on cutting up a fish and throwing pieces of the various organs overboard, it was found that everything sank except the liver and the skin. The liver floats no doubt because of the large quantity of fat it contains. The skin is 2-2½ inches thick and, the fish being flat, forms a large proportion of the body: it is evident that the fish floats passively on account of this buoyant jacket.

The skin is made of a tough elastic material, slimy to the touch, resembling rather soft cartilage: as a whole it is stiff enough to form what may be described as a rigid coat. For more detailed examination a number of slices were preserved in sea-water formalin: the slices had not changed in their appearance or proportions, and this pickled material probably represents fairly the fresh condition apart from such features as the solubility of the mucus, etc. The epidermis is 1-2 mm. thick; internally the skin is bounded by the very thin parietal peritoneum: the rest is uniform in appearance and shows microscopically a felted mass of thin wavy fibres arising stellately from connective tissue cells. There are a few rather thicker straight fibres but nothing of the nature of trabeculæ or struts. A few canals—presumably mucous ducts—are found here and there. No stainable fat is present, nor can any be obtained from dried material by extraction with ether, chloroform, or petrol.

After washing out the salt in distilled water, the specific gravity of the substance of the skin was found to be 1013 to 1016 with a mean of 1014 by weighing in air and water and floating bits in salt solutions of different strengths. It is difficult to get very precise results since one has to start with pieces in the rather indefinite state of being "surface dry." The specific gravity of pieces soaked in 0·9 per cent. NaCl solution was 1021. This may be taken to be somewhat near the natural gravity since it is known that the concentration of the body fluids of teleostean fish corresponds with that of mammals and is much less than sea-water. Taking the gravity of sea-water as 1026, these figures are compatible with the observation that the whole fish is just buoyant.

The most remarkable thing is that the percentage of solids in the skin washed out in distilled water is only about 3·7 per cent., figures varying from 3·5 to 4·2 being given by different pieces while the loss of weight on drying *in vacuo* over sulphuric acid is practically the same as the loss in an oven at 95° C. Histologically the larger part of the skin substance appears to be made of connective tissue fibres, and it is extraordinary that 2 per cent. or less of the mucoid material can give, when it is swollen with water, a tissue the mechanical firmness and rigidity of the skin.

The specific gravity of the dried solids, by floating in chloroform-petrol mixtures, was 1·335. Calculation from this gives a specific gravity of 1010 or thereabouts for the undried material. The difference between this and the determined value of 1014 (involving a value of about 1·6 for the solids) may be an error of observation or indicative of a condensation of the mucoid material when it is swollen in water, such as is known to occur with starch, gelatine, and proteids (Chick and Martin, *Biochemical Journal*, vii. (1913), 92).

After formalin fixation, the mucus is not soluble in dilute sodium carbonate, and once the skin has been dried *in vacuo* it will not swell up again in water, dilute acid or alkali.

Thursford, East Cowes.

Haloes and Earth History.

IN continuation of my letter on this subject in NATURE of April 22, p. 517, fifty additional measurements of the small Ytterby haloes have been made. The same consistency among the readings is noticeable. The mean result is a radius of 0·0052 mm. Introducing two corrections not previously applied (for the somewhat higher stopping power of this mica and for the fact that in such measurements we do not generally deal with the extreme range) I find that the range in air might be as much as 1·4 or even 1·5 cm. The nuclear correction would reduce this a very little.

The consistency of measurements among these haloes is, I think, even greater than would be found to obtain among normal haloes. The law prevailing among halo-dimensions is only apparent upon comparison and classification. It is by no means *prima facie* evident. It was just for this reason that it for so long escaped notice.

There is evidence that some of the larger sized Ytterby haloes deserve consideration as constituting a true radioactive development. Their radius is consistently 0·0086 mm. The nucleus is far too small to account for the difference. With all allowances (save that for the nucleus) this comes out as 2·4 cms. in air at 15° C. This is suggestively like that of UI (2·50). But we seem debarred from the tempting conclusion that hibernium may be a proto-uranium by the time-difficulties involved.

The paragraph in my letter referring to the possibility that the Ytterby haloes might date back to a prior geological era requires some explanatory amendment. It would be better to speak of the Archean as what (as I believe) it really is—the record of a past geological era; a material record finally brought to an end by thermal changes sufficient to evaporate the oceans. The reading of the halo—could we read it aright—would then assign a date to the formation of the containing mica. Upon the *prima facie* evidence this date is very remote. That is all I have to say upon this point.

There are, as I have intimated, possible alternatives to the view that very great time intervals are involved. The element responsible may emit α-rays the connection of the range of which with the radioactive

constant may involve a very different constant from that which, with small modification, applies to the three known radioactive families. Still more fundamental would be the discovery of some other than a radioactive origin for these haloes. I have considered many alternatives. One naturally thinks of a chemical influence emanating from the nucleus. Apart from the difficulty of accounting for the consistent measurements, the existence of bleached haloes in this mica, which possess the characteristic dimensions of uranium and emanation haloes, seems a formidable difficulty. The relation between the radioactive staining and the bleaching is everywhere such as to suggest that the latter is a modification of the former. A quantitative difficulty also exists. The volume of the nucleus varies from the $\frac{1}{5000}$ to the $\frac{1}{15000}$ part of the halo-volume which it has affected. Yet the nucleus may be a limpid particle revealing no trace of loss or decomposition. Only radioactivity can confer on one atom the energy requisite to ionise many hundreds.

Of course some one of the known elements may be responsible for these haloes. Geiger and Nutall long ago pointed out the difficulty which would attend the discovery of radioactivity in elements having a radioactive constant proportional to such ranges. But here we have an integration such as far transcends the resources of the laboratory. Until this point is settled—if it ever will be possible to settle it—a distinguishing name seems desirable. To this name the addition of numerals would suffice to deal with such halo-developments as may be ascertainable.

J. JOLY.

Trinity College, Dublin, April 25.

Pythagoras's Theorem as a Repeating Pattern.

THE interesting communication from Major MacMahon on the above subject reminds me of a proof which I discovered over the chessboard a few years ago, of the well-known fact, that if the lengths of the sides of a right-angled triangle are 3 and 4, the length of the hypotenuse will be 5.

Placing pawns at A, B, and C (Fig. 1), we require to prove that A is equidistant from B and C. We put

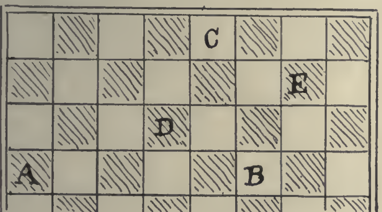

FIG. 1.

two more pawns at D and E, when it will be readily seen, even by a person unacquainted with Euclid, that A, D, E are in line and that CEBD is a square. Since any point on a diagonal of a square must, by symmetry, be equidistant from the extremities of the other diagonal, AB = AC.

The corresponding general proof of Pythagoras's theorem is as follows. Given $x^2+y^2=z^2$, we get

$$\frac{z+x-y}{x+y-z}=\frac{x+y+z}{z+y-x}. \qquad (1)$$

by algebra. Taking horizontal and vertical axes of reference through an origin O (Fig. 2), we mark down a point A the co-ordinates of which are $\frac{1}{2}(z+x-y)$, $\frac{1}{2}(x+y-z)$, and a point B the co-ordinates of which are $\frac{1}{2}(x+y+z)$, $\frac{1}{2}(z+y-x)$. By the given relation (1) OAB is a straight line. Through A and B draw ordinates PQ, SR, each equal to PS, and in the square PQRS inscribe the square ADBC by marking off RD = PC = SB. Then, drawing the ordinate DN, we have

$$DN = PS = \tfrac{1}{2}(x+y+z) - \tfrac{1}{2}(z+x-y) = y,$$
$$ON = OP + PA = \tfrac{1}{2}(z+x-y) + \tfrac{1}{2}(x+y-z) = x,$$
$$OD = OC = OP + SB = \tfrac{1}{2}(z+x-y) + \tfrac{1}{2}(z+y-x) = z,$$

which proves the theorem.

It is to be noted that in any special case where x, y, z are given integers (as in the case given above), it can be easily shown that OAB is a straight line

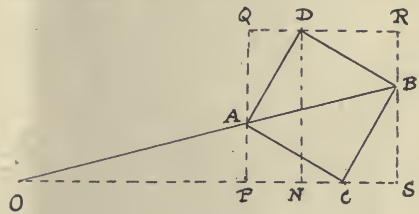

FIG. 2.

without knowing anything about proportion. Thus in such cases Pythagoras's theorem is proved without introducing areas. It has, I believe, been suggested that the ancient Egyptians must have been acquainted with Pythagoras's theorem, since they knew that a triangle with sides 3, 4, 5, is right-angled. But they may possibly have known only the special proof here given.

Lastly, it may be noticed that Euclid's axiom about parallels is tacitly assumed when we allow that a repeated pattern of squares can be constructed.

J. R. COTTER.

Trinity College, Dublin, April 15.

Man.

MAN is a social animal through habit, not instinct. Religions, morals, taboos, customs, conventions, which he learns through imitation, supply him with rules of thought and conduct. Without them human society could not exist. But there are two sorts of rules. The one kind binds the body, limits action, supplies rules of conduct, and impels men to "play the game" fairly. The other sort binds the mind, limits thought, impels men never to question the rules. *When the rules that bind the mind are many and strait, men tend to regard lightly the rules that bind to conduct.* All this may seem far-fetched, but consider universal history. Is it not the fact that communities have been inefficient, stagnant, and turbulent in proportion as their minds have been bound?

I may be afflicted with racial prejudice, but to me it seems that the men of English speech owe their predominant position in the world to the fact that they more than others "play the game" scrupulously, and yet have been freest of all in their thoughts, and so, while obeying their existing rules, have most readily altered the rules both of conduct and of thought. We English may have only one sauce, but, fortunately, we have a hundred heresies. Modern English history tells of continuous evolution, but of only one revolution. Compare the histories of more orthodox countries. Men cannot get away from habit, and mental habits depend not so much on the things that are learned as on the way in which they are learned. Through imitation we get emotional convictions and closed habits of mind; through curiosity, intellectual convictions and open, reflective habits of mind. When a man is mentally "too old at forty" his mind has been artificially closed. It can no longer profit from experience.

He has become unintelligent. Consider the unlike results which would follow the teaching of science on the grounds of faith and of evidence. In the former case there would be stagnation, passionate and unending controversy, with deference to this authority and hatred of that; in the latter case, contempt for mere authority, efficiency, progress, cool discussion, and ultimate agreement. Always it is not so much the thing that is taught that matters, but the way in which it is taught, through imitation or through curiosity. Consider how inefficient were such nations as Russia and Turkey in the late war, and how they are smashed beyond repair. Had the peoples of the world been less prejudiced and more intelligent there would have been no war. The subject is immense, and desire for compression has made me didactic; but readers of NATURE may fill lacunæ, and perhaps forgive my manner.

Men learn, through imitation, unlike standards. Among us are people who regret the Dark Ages: as before them there were doubtless those who regretted the manly times of Saxon piracy, and before them those who grieved for painted savagery. But, obviously, if we desire intelligence, efficiency, a contented and prosperous population, and a progressive civilisation, we must teach our youth as much as possible through evidence. We cannot help imparting some things through imitation (*e.g.* our ideas of right and wrong), but our special aim should be to create through curiosity an open, reflective habit of mind. This is, of course, the way in which science has been created, and which its workers constantly advocate. But it is vain to express mere opinions. Many people who professedly, indeed sincerely, seek the same ends think it primarily essential to close the mind to evil by teaching especially the emotional convictions they may happen to hold, and to expend the rest of the pupil's time by causing him to learn through labour other things (*e.g.* languages) which are commonly acquired through imitation. A man may learn all the languages in the world and yet not part from a single prejudice.

Fortunately, the history of society furnishes crucial examples in abundance. For example, the modern world, like the Græco-Roman, but unlike every other, has been prolific in men great in thought or action. In these two worlds men have learned especially through curiosity. With very rare exceptions, only Christians (who more than others have abandoned mere imitation) have produced great men; and among Christians great men have been almost limited to the less orthodox (*i.e.* less imitative) sects, or to defaulters from the more orthodox. Consider Newton, Darwin, Napoleon and his contemporaries, Garibaldi, Bismarck, and the rest. The crime-rate of modern communities, ranging from civil war and rebellion, through brigandage and murder, to acts of petty violence, is immensely higher among the more orthodox, who, both peoples and individuals, usually occupy inferior positions and attribute their misfortunes to oppressors, native or foreign. But emigration to other lands leaves such people unchanged, as witness the alien population of Great Britain and the United States, with its emotionalism, tendency to corruption, and high crime-rate. Government by the orthodox is invariably corrupt or inefficient, or both, as in Russia, Turkey, and medieval England.

Efficient modern Governments, hoping to obtain peace, are often pathetically anxious to confer self-government on the orthodox. But you cannot make a silk purse out of a sow's ear. As object-lessons, compare Russia and Germany in defeat. The latter, wrecked by an emotional despot and his Byzantine Court, is cleverly reconstructing her prosperity. Russia was, and is, and will long continue, an autocracy or lapse into chaos. People with the degree of intelligence permitted by the Orthodox Church could not possibly evolve a free and orderly State. Consider all the nations of the world. Invariably you will find that the men whose rules limit thought are inferior to those whose rules, relatively speaking, limit only action. Many empires have perished in the past from internal decay or external pressure. In the former case the decay has always coincided with an increase of training through imitation; in the latter, rival nations have increased their training through curiosity. We may confer self-government on populations in India, Egypt, and nearer home; but very certainly these populations will then only reproduce societies like those which people similarly trained have produced elsewhere.

Science has endowed humanity with a vast command over Nature, but has been less successful in establishing the scientific spirit. Within the limits created by his prejudices, facts may be taught to the adult, but frames of mind, as a rule, only to the very young; and science has neglected to consider the education of the latter. It is one thing to discover the shape and age of the earth or the origin of species, and quite another thing to persuade men already biassed to accept the intellectual consequences. It is one thing to invent explosives and aeroplanes, and quite another thing to make men, already made creatures of emotion through imitation, tolerant, reflective, open-minded, rational, so that discovery shall not be used for evil. The world is seething with passionate hatreds, the offspring of prejudices, which are derived from imitation. Consider the moral and religious differences which are indelibly impressed on the minds of children, and are the root-causes of nearly all the trouble that ferments from Galway to Singapore. Knowledge, the child of Science, has outgrown her twin Wisdom, and in the hands of violent and intolerant men may easily bring our civilisation to ruin. Consider ancient Rome and how exactly her decline coincided with the rise of fanaticism. Compare, as revealed in their literatures, the minds of the fervid saints with those of the common-sense pagans. But at least we may try to guard our own land. We have a unique opportunity; for among the British, the least prejudiced of moderns, are many who would accept crucial evidence concerning the development of society if it were offered fearlessly and insistently, and only the followers of science can so offer it. The main difficulty lies in the beginning: it will be hard to move scientific men, especially biologists, to action. From the nature of their training they lack enthusiasm (which is an emotion), and therefore organisation, and therefore power. Compare Salvationists. The little finger of General Booth is thicker than the loins of the president of the Royal Society. But probably, were the movement in favour of a right method of mental training well started, the laity would supply the enthusiasm. However, all that is on the knees of the gods.

I now conclude my letters to NATURE. They may, perhaps, have achieved some small success in things about which I care little, but probably none at all in the things about which I care much. I think they have been misunderstood. I am not wildly concerned about biological terminology *per se*, or about chromosomes, or whether groups of naturalists limit their facts to those furnished by zoology and botany, or experiment, or biometry, and so forth, or whether they bring a wider range of evidence from other sciences and studies into court by means of crucial testing. If the public be uninterested or stupid, it matters not how biologists divert themselves. If it be interested and intelligent, it matters supremely; but

in the latter case biologists will be compelled, by pressure from outside, especially from the followers of other sciences, to adopt the right methods, whatever they may be. But I am concerned with mind and education, and the moment one tries to reach bed-rock in such matters one finds oneself in biological quicksands. One is told that some characters are innate and some acquired, but not the distinction between the innate and the acquired. It is understood that things that are learned are acquired, but apparently no one has tried to ascertain how much is learned or how it is learned. Seemingly, all biologists are agreed that, in themselves, acquired characters are trifling things; but while Lamarckians think them important through their cumulative effects, neo-Darwinians, conceiving them as transient, think them unworthy of study. Both parties mean one thing when they apply the word "inherit" to "innate" characters, and the exact opposite when they apply it to "acquirements."

Man is the educable animal, say some biologists. He is not educable, say (in effect) others who declare that in his mental make-up nature is four, perhaps nine, times more potent than nurture. One admires the precision of statement, but wonders what is meant. As I understand it, man's nature is such that he is particularly responsive to the nurture of mental use. It is as if a physicist had stated that the steam is four, perhaps nine, times more potent than the engine. And so on. Meanwhile, prejudice controls education and society flows towards the cataracts. I may be very ignorant as to facts and mistaken in my opinions, but in that case my demolition should be a holiday task to the trained and learned intellect. Failing demolition, I cannot help believing that biologists do not realise how very great their science is, or might be, and how vitally and immediately important their labours are, or should be. Incidentally, I have sought in these letters of mine to indicate the high importance, as it appears to me, of classifying characters, not as innate and acquired, but, as physiologists do, according to the stimuli which cause them to develop. So far as I am able to judge, unless scientific men ascertain precisely how mental characters are developed, and then vigorously apply their knowledge for the betterment of education, modern society will soon be on the rocks.

Configurations of Molecules of Benzenoid Substances.

PROF. ROBINSON'S remarks (NATURE, April 15, p. 476) on Sir William Bragg's representation of the naphthalene molecule, as it occurs in crystals, lead me to invite attention to results obtained recently by Mr. G. H. Christie and myself. In a paper which will be published in the forthcoming number of the Journal of the Chemical Society, the resolution of *trans*-6 : 6′-dinitro-diphenic acid into optically active components is described. This, with the fact that an apparently homogeneous brucine salt has been obtained from the *cis*-form of the acid, indicates that in the separate molecules (as distinguished from their crystalline aggregates, to which Sir William Bragg's results apply) of these compounds the two benzene nuclei are not coplanar.

If this be so, it follows that the direction of the valency of each of the carbon atoms through which these nuclei are united is not, as represented in the usual formulæ for benzene, exerted in the plane of the benzene ring, and further, that this condition is a stable one rather than a phase of an oscillation of the type referred to by Prof. Robinson. It may be possible to determine to what extent, if at all, this stability involves a modification of the normal benzenoid properties associated with two benzene nuclei. Differences between diphenyl itself and benzene in respect of their molecular refraction, and behaviour on catalytic reduction and towards ozone, are already on record, so that it will also be pertinent to inquire whether the fixity of configuration is a general property of diphenyl derivatives, or is dependent on the nature of the substituents present, and connected, for example, with the observations of Baly and Collie (Trans. Chem. Soc., 1905, 1339) on the modification of the ultra-violet absorption of benzene by the introduction of a nitro group.

In any case, our result would appear to supply the first direct experimental proof that other configurations of the separate benzene molecule may exist than the plane (Kekulé) type. For the great majority of chemists, who also recognise the merits of the Kekulé formula, or some modification of it, this will involve the acceptance of some dynamic conception, such as, for example, has been advocated by Collie and by Bloch. It will be noted that one phase of Bloch's formula corresponds closely to that deduced by Sir William Bragg from his observations on the diamond and on naphthalene and its derivatives.

It should perhaps be pointed out that the above suggestions depend for their validity on the assumption that the relationship between the isomerides is stereochemical in the ordinary sense. There is always a possibility, which, however, will perhaps be generally considered remote, that the difference may be rather one of structure, in that the two compounds contain, for example, different types of nuclei.

J. KENNER.

The University, Sheffield, April 21, 1922.

The Speed of Light.

IN a discussion in NATURE last year (March 10, vol. 107, p. 42) Majorana's experiment was cited as direct proof that the velocity of light is independent of the motion of the source. In reality, however, there is a disadvantage in his method which seems to the writer very greatly to lessen the value of his results.

Majorana measured the wave-length of the green light from a moving mercury-vapour tube by means of a Michelson interferometer, and detected the change of wave-length that is required by the usual Doppler theory (*Phil. Mag.*, 37, p. 145, 1919). Now it is easily seen that the frequency of the waves arriving at the receiving apparatus will undergo the usual Doppler change whether the speed of propagation is altered (moderately) or not, and speed equals wave-length times frequency, hence Majorana concludes that the speed of the light from his tube was the same when the tube was moving as when it was at rest. But obviously he measured the wave-length only after the light had suffered one or two reflections or transmissions in stationary apparatus, and its velocity might easily have been altered by these processes. Any conclusion from his results must therefore rest, at best, upon very indirect reasoning.

We may freely admit that a satisfactory emission theory consistent with all the facts that are known to-day, including Majorana's result, would be difficult to construct. Yet it does seem regrettable that we have still no simple direct proof of the second postulate of Relativity.

Perhaps the simplest way to test the postulate directly would be to observe the Doppler effect with a concave reflecting grating so set as to form the image on the normal to the surface of the grating (cf. Tolman, *Phys. Rev.*, 35, p. 136, 1912); the retardation then occurs entirely before reflection, and it is the wave-length of incident light which is measured by the deviation. Any uncertainty as to the relative speed of the reflected rays can be removed by making the line of motion of the source pass through the centre of the grating, and then observing the effect of the motion upon the position of the central image when the grating is turned so as to bring this image into the position formerly occupied by the diffracted one. In these circumstances, for reasons of symmetry the speed of the incident waves along two rays equally inclined to the direction of motion must be the same; if it then turns out that the position of the central image is unaffected by the motion, it will follow that the speed must likewise be the same along the two corresponding reflected rays. This conclusion will hold also for the two diffracted rays which take these paths in the main experiment.

Department of Physics, Cornell University.

On the N-Series in X-Ray Spectra.

WITH the new and very powerful X-ray-spectroscopic outfit constructed by Prof. M. Siegbahn (described in *Comptes rendus*, 1921, p. 1350) I have endeavoured to find a weaker group of lines in the X-ray region than the lines previously known as M-group. I have been able to find some lines which most probably must be referred to the N-series of the elements uranium and thorium. Hitherto, the measured wave-lengths for these lines lie for uranium between 8·6-12·0 A.U. and for thorium between 9·4-13·5 A.U.

From the theoretical and experimental work done by Coster and others, we are able to estimate the wave-lengths of the lines in the N-series. For the elements uranium and thorium we really find that some of these lines must have wave-lengths of about the measured value. For bismuth, however, and the elements in its neighbourhood, all the N-lines must have a wave-length of more than 13 A.U. so that in the present state of spectroscopy it will be very difficult to measure the wave-lengths for these elements.

I am continuing these researches.

A Proposed Laboratory Test of the Theory of Relativity.

WITH the present interest so strong in devising experiments to test the theory of relativity, it may not be amiss to suggest the possibility of yet another method. According to recent hypotheses, it seems that the stars are the factories producing complex elements from simpler structures. Inside the stars, hydrogen atoms may unite to form helium, and with hydrogen and helium as intermediates, the more complicated atoms may be built. As pointed out by Harkins, Eddington, Perrin, and others, the synthesis of an atom of helium from four hydrogen atoms necessitates the loss of 0·774 per cent. of the mass of the hydrogen atoms. Since we cannot conceive of mass being annihilated, the only obvious solution is to say that mass is electromagnetic in origin and that, in the helium nucleus, the four protons are brought so near to the two electrons that their fields overlap and neutralise each other to some extent, accompanied by a loss of mass. According to the theory of relativity, 1 gram of matter is equivalent to 9×10^{20} ergs or $2\cdot1\times10^{13}$ calories. Both Harkins and Perrin have calculated the amount of heat that must be produced by the transformation of four gram atoms of hydrogen into one gram atom of helium. It has the enormous value of $0\cdot0078\times2\cdot1\times10^{13}$ or $1\cdot6\times10^{11}$ calories.

It may be possible for several helium nuclei to unite to form heavier nuclei, such as oxygen for example, without such a great evolution of heat. More accurate determinations of the atomic weights of the so-called "pure" elements would be necessary before we could say much concerning the energy relations in such sub-atomic reactions.

When the nuclei become so large that they are unstable, then the process of synthesis in the stars would stop. But there might be an over-shooting of the mark. With the enormous amount of energy free in the interior of the stars, some of this energy might be absorbed, according to the theorem of Le Chatelier, in the formation of nuclei which would be unstable in an environment not containing so much energy. Energy would be considered as one of the terms in a mass law equation, to use a well-known chemical analogy. The result would be the radioactive elements—uranium, thorium, etc.

Now let us calculate with the aid of the above equation, derived from the theory of relativity, the effect on the mass of a radioactive substance that would be caused by this addition of energy. Rutherford, in his book "Radioactive Substances and their Radiations," p. 582, states that 1 gram of radium in disintegrating to lead gives off $3\cdot7\times10^{9}$ calories. If 1 gram of mass $=9\times10^{20}$ ergs $=2\cdot1\times10^{13}$ calories, then 1 gram of radium in disintegrating to lead would give off 0·00017 gram and 1 gram atom of radium, 0·038 gram in the form of energy. If the atomic weight of RaG (radium-lead) is taken as 206 exactly, then the atomic weight of its parent, radium, may be calculated as follows:

1 gram atom of RaG	206·000	grams
5 gram atoms of He	20·000	,,
4 gram electrons	0·0005	,,
$3\cdot7\times10^{9}$ calories	0·038	,,
	226·038	,,

Therefore the atomic weight of radium should be 226·038. Calculations of this type for radioactive substances have been made by Harkins, but he does not state that they may be applied as a test of the theory of relativity.

This calculation involves six assumptions: (1) that the weight of one gram atom of RaG is 206·000, (2) that the atomic weight of He is 4·000, (3) that the weight of 4 gram electrons does not exceed 0·0005 by any great extent when incorporated in the nucleus of Ra, (4) that the amount of energy given off in the disintegration of Ra is substantially that calculated by Rutherford (a 20 per cent. decrease in the value given by him would not change the value for energy in grams in the second decimal place), (5) that the relativity equation connecting mass and energy holds, and (6) that the energy given off in radioactive disintegrations is derived from the atoms themselves and not photochemically from Perrin's hypothetical radiations of extremely short wave lengths. In trying to verify the results of such an equation, there are two more assumptions necessary: that the atomic weights of RaG and of Ra are determined for the pure substances, that there are no contaminating isotopes.

The lowest atomic weights of RaG that have been obtained are those of Richards and Hönigschmid, and are 206·08 and 206·05 respectively. These may be a little high due to admixture of other isotopes of lead. The best value for the atomic weight of radium is 225·97 by Hönigschmid, but the difficulties due to incomplete purification and small quantities of material worked with probably make this value less accurate. Nevertheless, if this figure for radium is accepted provisionally, one must conclude that either radium-lead (RaG) has an atomic weight less than the whole number 206, or that the energy is derived from outside sources as suggested by Perrin, or that the equation connecting mass and energy is not correct.

Now I will suggest a more exact method of testing experimentally the above calculation of the atomic weight of Ra. It is evident that the chemical determinations of the atomic weights of Ra and RaG cannot be made with sufficient accuracy due to difficulties inherent in such determinations and to the probable presence of isotopes in the samples used. When the method of positive ray analysis is extended so that it is accurate to 1 part in 10,000, then we would have a method of determining the masses of Ra, RaG, and He with sufficient accuracy. This refinement does not seem utterly impossible. Though the method is relatively in its infancy, yet Aston claims in the case of helium an accuracy of 2 or 3 parts in 1000. By the positive ray analysis all difficulty with contaminating isotopes in the case of RaG and Ra would vanish. The calculated atomic weight of Ra could be checked by data thus obtained, and the conclusions ought to show whether the relation of mass and energy based on the theory of relativity holds. In any case, the results would be valuable.

Safeguarding of Industries Act, 1921.

From time to time complaints have been made in Nature and received at the offices of this Union against the operation of the Safeguarding of Industries Act, 1921. It has been asserted that the Act greatly increases the running cost of laboratories, which are still, to some extent, dependent upon other countries for supplies of scientific apparatus, laboratory ware, and fine chemicals; and this increased cost has fallen upon research and teaching institutions at a time when the Government is restricting grants.

In consequence of the complaints received, this Union approached the British Medical Association, and a joint committee of the two organisations was formed, with the view of exploring the ground, and making representations in the proper quarters. If sufficient information is forthcoming, it is the intention of these two associations to arrange for a deputation to wait upon the Rt. Hon. H. A. L. Fisher, Minister of Education, following upon the suggestion made by Viscount Peel in the House of Lords on November 10 last. It is intended that this deputation should be representative of all scientific and educational bodies, and we are already assured of the support of some of them.

A letter has been addressed to the Deans of the Faculties of Science and Medicine of all British Universities and University Colleges, to Deans of Medical Schools, to Principals of Technical and Agricultural Colleges, and to the Institutes of Physics and Chemistry, and the various teachers' associations. This has asked for information under the five following headings:—

"1. The difficulties experienced by members of your" [University, society, etc.] "in obtaining British materials and laboratory ware of the requisite quality and quantity.

"2. The difficulties experienced in obtaining British scientific instruments.

"3. Detailed particulars of instances where difficulties and delays have been experienced through the action of the customs authorities, in obtaining consignments from abroad. (*N.B.*—It would be well to indicate here from which countries the greater bulk of the goods are obtained.)

"4. The increase in the running costs of laboratories which can be directly attributed to the operation of the Act.

"5. Details of cases where researches have been hindered or had to be definitely abandoned owing to the difficulties of obtaining materials from abroad or their excessive cost in this country."

A fair number of replies has been received, though in many cases the information given is not in sufficient detail. I should be glad, therefore, if all scientific workers, including those engaged in industry, would supply me with detailed information under these five headings at the first opportunity.

Discovery of Gold in Devonshire.

I had occasion recently to conduct a party of my students from King's College, London, over the Devonian rocks in the neighbourhood of Torquay, Devon, and had the good fortune to discover an interesting occurrence of gold in the fault-rock of a small fault cutting the limestones near Hope's Nose. As it may prove of some interest, I take the opportunity of recording the find in the columns of Nature.

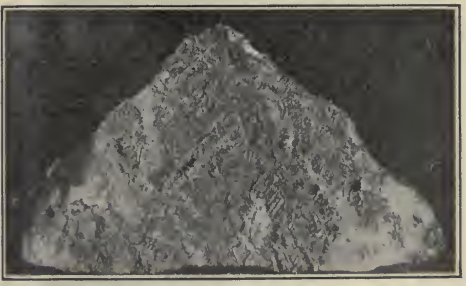

Fig. 1.—Dendritic gold in Devonian limestone. (×3.)

The fault-rock is a limestone-breccia cemented by crystalline calcite, through which the gold is distributed in a dendritic fashion, as indicated in the accompanying figure (Fig 1). It is premature to dogmatise on the possible commercial value of the gold, since time did not permit of a thorough examination of the locality, and a former find at Daddy's Hole proved too poor to work, but it is intended to proceed further with the matter in case it may prove worth exploitation.

W. T. Gordon.

Artificial Disintegration of the Elements.[1]

By SIR ERNEST RUTHERFORD, F.R.S.

SINCE the development of the atomic theory on an experimental foundation by Dalton, the progress of chemistry has been based on the central idea of the permanency and indivisibility of the atoms of the elements. The whole experience of chemistry for nearly a century had shown clearly that it was impossible to break up the atoms of the elements by the application of ordinary chemical and physical processes. This idea has had to be modified to some extent by the rapid growth of our knowledge during the last twenty years of the inner constitution of the atoms.

It is now generally accepted that the atoms of the different elements have all the same general type of structure. At the centre of the atom is a positively charged nucleus of minute dimensions which is responsible for most of the mass of the atom. This is surrounded by a distribution of electrons held in equilibrium by the forces from the nucleus. The electrons occupy rather than fill a region the diameter of which is of the order of 2×10^{-8} cm. The nuclear charge of the atoms follows a very simple rule first clearly brought to light by Moseley. The resultant nuclear charge of an atom is equal to its atomic or ordinal number, and varies from 1 "atom" of electricity in the case of hydrogen to 92 in the case of uranium. These ordinal numbers represent also the number of "planetary" electrons, as they have been called, which surround the nucleus of the atom. On this view of the atom, its ordinary physical and chemical properties, apart from its mass, are governed entirely by the nuclear charge, for this controls the number and arrangement of the external electrons on which these combining properties mainly depend. The mass of the atom is a property of the nucleus and exercises only a second order effect on the distribution of the electrons and so on the ordinary properties of the atom.

This point of view offers at once a simple explanation of isotopes, which consist of atoms of the same nuclear charge but of different nuclear masses. By the action of light and electrical discharges, we can readily remove one or more of the external planetary electrons from the atom, while by the action of X-rays and swift β-rays we may even eject one of the more strongly bound electrons of the system. In this way, we can effect, in a sense, a transformation of the atom, but it is merely a temporary one, and a new electron is soon captured from outside, and the atom is as before. The general evidence indicates that, even if a number of the planetary electrons were removed by suitable agencies, the stability of the nucleus would not be disturbed and the atom would in a short time regain its original structure. In order to effect a *permanent* change in the atom, it appears to be necessary to disrupt the nucleus itself. When once a charged unit of the nuclear structure is removed, the nuclear charge is altered permanently, and there is no evidence that this process is reversible under ordinary experimental conditions.

The discovery of the instability of the radioactive elements was the first severe shock to the idea of the permanency of all atoms. This radiating property is, however, confined mainly to the two heaviest elements, uranium and thorium, and their long series of descendants, and is shown only by two other elements, potassium and rubidium, and then only to a minor extent. Apart from these exceptions, the great majority of the atoms appear to be exceedingly stable structures, and to remain unaltered under ordinary conditions in this earth for periods of probably thousands of millions of years.

The property of radioactivity belongs to the nucleus, and is shown generally by the emission of a swift α-particle or helium nucleus and, occasionally, a swift electron or β-ray from the nucleus. The number and velocity of emission of these particles appear to be quite uninfluenced by the most powerful physical or chemical agencies, and to be an inherent property resulting from the instability of these very complex nuclei.

These results show clearly that the nuclei of heavy atoms contain both positively charged helium nuclei and negative electrons, and lead to the general view that the complex nuclei of all atoms are built up of hydrogen and helium nuclei and electrons. It is also generally supposed that a helium nucleus itself is a secondary unit composed of four hydrogen nuclei and two electrons. If this be the case, we may suppose the nuclei of all atoms to be composed ultimately of hydrogen nuclei, or "protons," as they have been termed, with the addition of negative electrons.

Radioactivity has thus not only provided us with the key of the structure of the elements, but has at the same time given us in the swift α- and β-particles a powerful method of probing the inner structure of the atom. By firing α-particles into the atoms of matter, we are able, by following the deflexions of the path of the α-particle, to find out the magnitude and law of the forces close to the nucleus and to form some idea of the dimensions of the latter. The general results suggest that the diameter of the nucleus of heavy atoms is of the order of 4×10^{-12} cm. or about 1/5000 of the diameter of the whole structure of the atom. The law of the inverse square of repulsion between electric charges is found to hold for a considerable region surrounding the nucleus. No doubt the size of the nuclei of light atoms is even smaller, and in the case of helium appears to be of the order of 5×10^{-13} cm. It is thus clear that the nuclei of atoms, although of very complex structure, are of exceedingly small dimensions.

It is probable that the forces which bind together the components of the nucleus are exceedingly powerful, and that consequently a large amount of energy will be required to disrupt its structure. The swift α-particle from radium or thorium, which is by far the most concentrated source of energy known to us, seems the agent most likely to succeed in an attack on the strongly-bound nucleus. The α-particle is expelled from radium with a velocity of about ten thousand miles per second, and thus has a speed twenty thousand

[1] A Lecture delivered before the Chemical Society on February 9.

times greater than that of a swift rifle bullet. Mass for mass, its energy of motion is four hundred million times greater than that of the bullet.

Whilst no doubt an α-particle fired directly at a heavy nucleus may penetrate its structure, its energy may at that stage be too small to cause a disruption. The attack on the lighter atoms is much more promising, for the repulsive forces are so much smaller that the α-particle may still retain much of its energy on entering the nuclear structure.

Before, however, considering experiments on this question, it is desirable to say a few words on the collision of α-particles with hydrogen nuclei, where no question arises of the disruption of the atom. When α-particles pass through hydrogen gas, there are occasional close collisions between the α-particles and the hydrogen nuclei, resulting in the appearance of high speed H-nuclei. These H-particles travel about four times the distance of the bombarding α-particle, and can be detected easily by the scintillations they produce on a zinc sulphide screen. From the ordinary principles of mechanics, the maximum speed given to an H-nucleus is 1·6 times that of the colliding α-particle, whilst the maximum energy communicated to it is 0·64 of the energy of the α-particle. It is found that the number of these swift H-atoms is far in excess of that to be expected if it be supposed that the α-particle and hydrogen nucleus behave as point charges for the very small distances involved in these violent collisions. In addition, the variation of the number with the velocity of the α-particle and the number shot off at different angles with the direction of the α-particle differ markedly from the results to be expected on the simple point theory.

It seems clear that not only has the α-particle a structure, but that the law of force at very short distances is entirely different from that of the inverse square. As a result of a careful investigation, Chadwick and Bieler concluded recently that the results of the collisions could be explained by supposing that the α-particle—to which the complexity is ascribed—behaves like a spheroid of axes 8×10^{-13} and 5×10^{-13} cm. Outside this surface, the law of the inverse square applies, but the forces increase so rapidly when the H-nucleus enters the spheroidal surface that it is rapidly turned back. This model of the helium nucleus is, no doubt, quite artificial, but it gives us some idea of its probable dimensions and the extent of the region in which new and powerful forces come into play.

We should consequently anticipate that, in a close collision of a swift α-particle with the nucleus of an atom more complex than that of hydrogen, the ordinary laws of force would break down when the distances separating the particle and nucleus became very small. It must be remembered that gigantic forces come into play in these nuclear collisions, and only very stable structures may be expected to survive the encounters.

The first observation which has to do with the main subject of my lecture was made some years ago. When the α-rays from a strong radioactive source pass through dry gases like oxygen or carbon dioxide, a small number of weak scintillations are observed on a screen beyond the range of the α-particles. These "natural" scintillations are believed to be due to atoms of hydrogen coming from the source, and probably result from a slight hydrogen contamination of the source during exposure to the radium emanation. If, however, dry air is substituted for oxygen or carbon dioxide, the number of scintillations is increased three or four times. This additional effect was found to be due to the presence of nitrogen, and was shown in a correspondingly greater degree by chemically prepared nitrogen. By suitable arrangements, it was found that the particles causing these scintillations were bent by a magnetic field to about the extent to be expected if they consisted of swift, charged H-atoms. It seemed probable from the beginning that these additional H-atoms, which appeared only in dry nitrogen and not in oxygen or carbon dioxide, must have their origin in a disintegration of the nitrogen nucleus by collision with a swift α-particle.

With the original counting arrangements, the scintillations were small in number, weak in intensity, and difficult to count with accuracy. Further progress has depended mainly on improvements in the counting microscope, with the object of increasing the intensity of the scintillations and the area of zinc sulphide screen under observation. By the use of wide-aperture objectives and special eyepiece lenses of low magnifying power, the counting of these scintillations has become much easier and more definite.

We shall now consider the methods adopted to investigate in more detail the effects observed in nitrogen and to test whether other elements behave in a similar way. The apparatus required is of the simplest character and consists merely of a brass tube, 3 cm. in diameter, provided with stopcocks by means of which dry gases may be circulated through it. At one end of the tube is a hole covered with a thin silver plate. The zinc sulphide screen is fixed 1·3 mm. away from the opening, leaving a slit in which absorbing screens of mica can be inserted. The radioactive source is fitted on the end of a rod so that its distances from the screen can be varied at will. In order to reduce the luminosity due to the β-rays from the source, the whole apparatus is placed in a strong magnetic field. It may be of interest to give a few details in illustration of the magnitude of the effects to be expected under different conditions. Suppose that the radioactive source, consisting of a brass disk coated on one side with an invisible layer of radium-C corresponding in γ-ray activity to 40 milligrams of radium, is placed 3·5 cm. from the screen and that a current of dry hydrogen is passed through the apparatus. Suppose the stopping power of the materials between the source and the zinc sulphide screen corresponds to 20 cm. of air, that is, it would suffice to stop an α-particle of range 20 cm. in air. The passage of the α-particles, which in this case have a range of 7 cm., through the hydrogen liberates a large number of high-speed H-atoms, which produce scintillations on the screen. Their number, seen through a special microscope which has a field of view of 40 sq. mm., is so great—thousands a minute—that it would be impossible to count them without reducing the activity of the source. As additional absorbing screens of mica are added, the numbers fall off rapidly, and for an absorption of, say, 30 cm. not a single H-scintillation can be observed per minute. A similar effect is shown if oxygen is substituted for hydrogen

and a thin strip of paraffin wax or other hydrogen material is placed over the source. The number of H-scintillations observed for a given absorption depends only on the amount of hydrogen, and is quite independent of chemical combination. This is to be expected, for the forces required to set the H-nucleus in rapid motion are enormous compared with the weak forces involved in chemical combination. We thus conclude that, for α-particles of range 7 cm., no H-atoms from hydrogen in the free state or in chemical combination can be detected for an absorption greater than 30 cm. of air.

The oxygen which gives no scintillations is now replaced by dry air. At once we observe for an absorption of 30 cm. more than 100 scintillations per minute when for hydrogen we did not observe one. By adding mica screens we find that the scintillations cease for an absorption of 40 cm. It is clear that these particles, which come from nitrogen, have a greater range than free H-atoms bombarded by α-rays, so that the effect observed beyond 30 cm. cannot be ascribed to any hydrogen impurity in the nitrogen.

The air is now replaced by neutral oxygen, and thin foils of say copper, iron, silver, gold of stopping power corresponding to about 3 cm. of air are placed successively over the source. Not a single H-atom can be observed for an absorption of 30 cm. A piece of aluminium foil is substituted and at once the number of scintillations jumps to more than 100 per minute. Some of the scintillations are very bright, and we find that some of the particles are so swift that the absorption must be increased to 90 cm. before the scintillations vanish. It is clear that aluminium must give rise to a number of very long-range particles.

Thus if we examine the number of scintillations beyond the range of ordinary H-atoms, we are quite independent of any possible contamination of hydrogen in the material under examination. This is a great advantage, for we need not concern ourselves about the purity of the material as regards hydrogen. In this way, Dr. Chadwick and I have examined a large number of elements to test whether they emit particles of range more than 32 cm. When the element was not available, a compound of the element with an "inactive" element like oxygen was used. The material in the form of a fine powder is dusted on a thin gold foil, an adhesive film being used so that the average absorption of the material corresponded with 3-4 cm. of air, and was then exposed to the source of rays. With the exception of helium, neon and argon, all the elements up to atomic weight 40 have been tested. No element of atomic weight greater than phosphorus, 31, was found to give any effect, although it should be said that only a few of the elements of higher atomic weight have so far been examined.

A list of the elements examined in this way, from lithium to sulphur inclusive, is given in the following table. The second column gives the number of scintillations per minute per milligram activity of the source, namely, radium-*C*, for an absorption of 32 cm. of air. These numbers afford only a rough comparison of the effects given by different elements, for the conditions of the experiment, for example, the thickness and distribution of the film of material, varied from element to element. The fourth column gives the approximate range of the particles.

Element.	Material.	No. of particles per min. per mg. for the microscope used.	Maximum range of particles in cm. of air.
Lithium	Li_2O	—	—
Glucinum	GlO	—	—
Boron	B	0·15	*ca.* 45
Carbon	CO_2	—	—
Nitrogen	Air	0·7	40
Oxygen	O_2	—	—
Fluorine	CaF_2	0·4	over 40
Sodium	Na_2O	0·2	*ca.* 42
Magnesium	MgO	—	—
Aluminium	Al, Al_2O_3	1·1	90
Silicon	Si	—	—
Phosphorus	P (red)	0·7	*ca.* 65
Sulphur	S, SO_2	—	—

In addition to these, the following elements of higher atomic weight were examined: chlorine as $MgCl_2$; potassium as KCl; calcium as CaO; titanium as Ti_2O_3; manganese as MnO_2; iron, copper, tin, silver, and gold in the form of metal foils. In no case were any particles observed of range greater than 32 cm. of air. The question whether any of these elements give particles of range less than 32 cm. has not been examined.

It will be seen that the elements which give scintillations for an absorption of 32 cm. are boron, nitrogen, fluorine, sodium, aluminium, and phosphorus. The numbers for boron and sodium were distinctly less than for the other elements.

(*To be continued.*)

The Royal Academy.

THE representative of NATURE looking for points of scientific interest amongst the fourteen hundred or so annual exhibits at the Royal Academy may be excused if he sometimes feels depressed and is reminded of the proverbial searcher after a needle in a haystack, in so few of the pictures do objects having any direct connection with science appear. It has in past years been remarked that purely scientific work does not yet appeal to the Academy artist, and it is necessary to turn for points of interest to nature scenes such as may be found in pictures of sea, sky, snow, and country life.

In snow scenes J. Farquharson frequently has successful effects and "The Edge of the Forest" (239) this year is quite up to his standard. Another good snow effect, in this case associated with water, is contained in "A Yorkshire Bridge in Winter," by F. E. Horne (884). A successful landscape somewhat of the Leader type, the central feature of which is a group of pine trees, is shown by Frank Walton in 591. It is a pity that there is only this one example of his work in the exhibition. The title which A. J. Munnings has chosen for No. 111 does not lead one to expect a landscape, but the setting of the portraits which give

the name to the picture is a wide expanse of country with distant blue hills in the background showing delightful lights and shades. The effect is spoilt rather than improved by the somewhat wooden sitters so obviously posing in the foreground.

Turning to agricultural scenes, the two ploughs seem out of place alongside the rick in "Farm Lands in Sussex" (459) while hay still lies in the field uncarted. Again in "Harrowing" (827) the crop seems to consist of heather, surely a somewhat unusual occupation.

In "A Summer Gale" (610) R. G. Brundrit has quite failed to convey the impression of a gale, ordinary cumulo-nimbus which might be associated with a shower being all that is indicated in the picture. The idea of a gale is introduced more effectively in Sir Arthur Cope's "An Evening in October" (750), though wind is not mentioned in this case. A very direct reference to the work of the Meteorological Office is made in "The South Cone" (250), though it is not indicated which of the two hundred gale warning stations round the British coasts is referred to. The warning seems to have been successful, judging from the flag at the masthead and the spray dashing against the shore, but the sea in the foreground, curiously enough, is scarcely rippled. The reference to a forecast in the title of 175, "A Hopeful Forecast," suggests further possibilities of reference to the work of the Meteorological Office, such as a forecaster studying the movements of Bjerknes' Polar Front, or plotting ships' observations received by wireless telegraphy from the Atlantic and deducing the probability of a week of fine weather. But any such expectations are destined to be disappointed, since what the picture reveals is a young lady with golf clubs tapping an old dial type of barometer, the hand of which is hard over in the "Set Fair" position.

Rain falling at a slant owing to the difference in velocity of upper and lower wind currents is a common sight, but Norman Wilkinson has shown the increase of wind aloft in a striking manner through the agency of falling rain in his picture of the King's yacht *Britannia* racing in a squall (395). The wind is blowing across the picture from left to right and making the yacht heel over until the mainsail is awash, while in a shower near by the rain slants backwards as it falls through air of diminishing velocity. One is almost tempted to commence calculating the rate of change of velocity with altitude.

An optical phenomenon figures prominently in "The Charcoal Burner's Hut" (632), where bright coloured rings surround the moon at a radius which is too small for a halo, while of unusual size for a corona; but such varied optical forms have been seen in the sky from time to time that it is unwise to dogmatise upon the unreality of this representation.

Adrian Stokes' "Sunset" (188) is suggestive of a sun pillar in the bright vertical extension above the sun, though it is improbable that a real sun pillar was the source of his inspiration. The moonlit scene in 80, "The Dead of the Night," is curious from the whiteness of the tower and wall in the moonlight and yet the absence of shadows where these would be expected under the trees.

Much interest naturally attaches to W. L. Wyllie's picture of the towing of the old *Victory* into her resting-place in dry dock. The execution of the water in Portsmouth Harbour is so good that the frame at the lower edge of the picture causes quite a shock, the eye being deceived by the reality of the representation. J. Olsson has a pleasant sea and island scene in the Scillies (42), which gains greatly over some former works by restraint in the use of brilliant colouring.

This year's exhibition is conspicuous for the number of portraits it contains, these forming a more than usually high proportion of the whole. It is gratifying to notice in a place of honour in one of the principal galleries, and adjacent to a painting of the Royal Wedding, a portrait of Sir Charles Parsons by Sir W. Orpen. Men of science are not numerously represented, and careful search was needed to disclose a tablet of Sir William Ramsay destined for Westminster Abbey and a silver medallion of Prof. James Thomson for Belfast University.

J. S. D.

Obituary.

SIR PATRICK MANSON, G.C.M.G., F.R.S.

THE death of Sir Patrick Manson, which occurred in London on April 9, has taken from the medical profession one of its most distinguished leaders. Born in 1844, and educated at his native University of Aberdeen, Manson decided to follow his calling in the Far East, and in 1866 went to Formosa, whence in 1871 he moved to China, where he continued during eighteen years. From the very beginning of his career Manson made the causation of disease his study. He was naturally interested in the elephantiasis so prevalent around him, but it was not until 1874, when he came home to marry a wife, that he learned fully of Lewis's discovery of a microscopic filaria (now known as *Microfilaria bancrofti*) in the blood of Indian sufferers from the chyluria often associated with that disease.

On his return to China he settled down to the study of "elephantoid" pathology, and began with a survey of the blood of a thousand Chinamen. Having satisfied himself that the microfilariæ found in the blood are the issue of parent filariæ locked up in the lymphatics of the host—a discovery in which, however, he was anticipated by Bancroft of Brisbane—and that they are embryos incapable of any further development in the blood, he saw that the series of events by which the microfilariæ living in the blood of one man became the adult filariæ living in the lymphatics of other men must take place in the outside world, and might possibly be initiated by some such free-ranging, blood-sucking insect as a mosquito. His selection of the mosquito was decided by his further discovery that the microfilariæ make their show in the cutaneous blood of their host only after sunset, when mosquitoes are active; in the daytime they flock to the host's lungs and central blood-vessels. In 1877, with the compliance of an infected Chinaman, he put his theory

to the proof and found that it corresponded with fact: the microfilariæ were sucked into the stomach of his mosquitoes, and some of them migrated into the insects' tissues and there underwent definite changes of growth and development, and were thus set on their course, *via* the infected mosquito, for infecting other human beings.

It must be borne in mind that Manson was a busy medical practitioner working, far off and alone, as he could find time, and without particular appliances. It is not surprising, therefore, that he did not follow the exact course taken by infected mosquitoes in transferring their infection to man. He was content to have demonstrated the essential realities of a great original conception, and to have established the great pathogenetic discovery—so pregnant with further possibilities of knowledge, so abundant in its practical applications to human welfare—that a common blood-sucking insect is *the essential factor* in the maintenance and dissemination of a widely-diffused parasitic disease.

In 1894, when he had left China, Manson found his opportunity of applying this great principle to the problem of malarial infection. He had followed all the work that had been done on the parasites of malaria since their discovery by Laveran in 1880, and he had come to the conclusion that the secret lay in the motile filaments extruded from forms of the parasite now known to be male gametocytes. Other observers regarded these filaments as degenerations: Manson interpreted them in the light of his filaria observations. He argued that as the forms that produce them are so persistent and resistant, the filaments must have some vital meaning; that since they are not produced until the blood has been shed, their destiny lies in the outside world; and that since they cannot get out spontaneously, they possibly are extracted and nursed—like the microfilariæ—by mosquitoes. This is Manson's mosquito-malaria theory, that inspired and guided Ross in his wonderful discovery of the sexual cycle of the malaria parasite and final solution of the problem of malarial infection. The theory has sometimes been referred to as if it were one of the several ingenious speculations that have attributed the spread of malarial fevers to mosquitoes: quite otherwise; it stands apart as a closely-reasoned working hypothesis based on known facts in the history of the malaria parasite and legitimate inferences from the history of *Filaria bancrofti*. Ross, writing with all the combined authority of an historian and a malariologist, says of it (NATURE, vol. 61, 1900, p. 523): "Manson's theory was what I have called it—an *induction*—a chain of reasoning from which it was impossible to escape. . . . I have no hesitation in saying that it was Manson's theory, and no other, which actually solved the problem; and, to be frank, I am equally certain that but for Manson's theory the problem would have remained unsolved at the present day."

Manson had retired from China in 1890 and settled in London. In 1894 he joined the staff of the Seamen's Hospital, and in 1897 was appointed Medical Adviser to the Colonial Office. He was now able to realise his lifelong dream of a school in London where medical men going to the tropics could acquire all the necessary craftsmanship that he himself had yearned after in his early days in China. In this design he happily obtained the countenance of Joseph Chamberlain and the co-operation of the Seamen's Hospital Society, and in 1899 the London School of Tropical Medicine was established under him at the Albert Dock. Here, until his retirement from all active practice in 1913, he radiated rather than imparted wisdom and inspiration to many hundreds of his younger professional brethren; and here, under his sage and benign influence, there grew up a sort of Mansonian tradition that for useful work in the tropics a medical man, though always a clinician at heart and a sanitarian in his general outlook, must be a biologist in his attitude to pathology and ætiology.

Manson's place in the history of medicine can be estimated only when we consider how much of what for convenience we speak of as "tropical disease" is due to animal and animalcule parasites, and to what extent those parasites are fostered and diffused by blood-sucking arthropoda. Men before Manson had speculated on the pathogenetic possibilities—or even probabilities—of predaceous insects, but no man before him had followed—or gone near following—a specific pathogenic organism into a specific predaceous arthropod and discovered what happened to it there. "The light of humane minds," says Hobbes, "is perspicuous words, by exact definition snuffed and purged from ambiguity": it is Manson's pre-eminent distinction to have been the first to discover a connected series of facts and to have recorded them in exact definitions purged and snuffed from ambiguity—which is the acquisition of science. With Manson's high achievements as an original investigator and a teacher we have to consider also his extraordinary influence as a most prescient clinician—and a clinician who never forgot the comfort of his patients: in all this, as in his large humanity and his benevolent attitude to his fellow-workers, he worthily upheld the ideal of Hippocrates; and I have often thought that, as the Father of Tropical Medicine, his name may, perhaps, have the same lasting fragrance as that of his immortal archetype.

A. A.

SIR A. B. KEMPE, F.R.S.

SIR ALFRED BRAY KEMPE, whose death occurred on April 21, was born in 1849, and educated at St. Paul's School and at Cambridge, where he was twenty-second Wrangler. His first contribution to the science of mathematics was in 1876, when, in a paper on a general method of describing curves of the *n*th degree by link-work, he laid the foundation of the excellent discoveries he was destined to make in "linkages"—a subject in which he took a lifelong interest. In 1877 he gave his well-known lecture, "How to draw a straight line," in which he traced the history of the connection between the straight line and linkages from the partially successful attempts of Watt, Richard Roberts, and Tchebicheff, to the practical solution of the problem by Peaucellier in 1864. Together with Hart of Woolwich Academy and Sylvester he had added much to the knowledge of the subject, and these additions he described with models.

A paper on conjugate 4-piece linkages followed in 1878, and some smaller papers, but Kempe's principal

contributions appeared in the years 1885–86. The "Memoir on the Theory of Mathematical Form" is a first-rate piece of work. Its avowed object is to separate the necessary matter of exact or mathematical thought from the accidental clothing—geometrical, algebraical, logical, etc.—in which it is usually presented for consideration, and to indicate wherein consists the infinite variety which that necessary matter exhibits. This long and thoughtful research shows that as a thinker Kempe perhaps resembled W. K. Clifford more than any one else has done in the world of science. This indeed was recognised by Spottiswoode, who, coming into possession of "Mathematical Fragments" which had been reproduced in facsimile from the papers left by Clifford, decided to send them to Kempe. He dealt with them, and finding inspiration in the graph theory which they contained he wrote a very valuable and suggestive paper upon the "Application of Clifford's graphs to ordinary binary quantics." Clifford had not at the time of his death succeeded in effecting this, and it required a man like Kempe who was well versed in the rapidly growing theory of invariants to accomplish it.

In 1894–96 Kempe was president of the London Mathematical Society. In his valedictory address he dealt in a thoughtful and learned manner with the question of defining the subject matter of mathematical science. He finally suggests the statement, "Mathematics is the science by which we investigate the characteristics of any subject matter of thought which are due to the conception that it consists of a number of differing and non-differing individuals and pluralities." Here we can trace the influence of his studies of mathematical form. He always tried to behold the objects of his thoughts in their lowest terms freed so far as possible from all extraneous matter, and it is greatly to be regretted that, shortly after vacating the chair, he became so busy with the duties thrown upon him by his acceptance of the position of chancellor to several dioceses that his direct contributions to science, from which much might have accrued, came to an end.

Indirectly, however, Kempe was for the remaining years of the greatest service to science. Those which he rendered to the Royal Society as treasurer have been described elsewhere. It must be added that from that position he was *ex officio* treasurer of the National Physical Laboratory from its foundation until April 1918, and he was able to do much for that great institution and for its director and executive committee. He never failed to attend particularly the finance committee, and was always fully informed as to the details of finance. His help and advice, often sought, was given ungrudgingly, and it may be said that it was owing largely to him that the funds necessary for maintaining and developing the laboratories were obtained. In the scientific life of the country he took a notable position. He was universally popular and respected. P. A. M.

SIR WM. PHIPSON BEALE, BART., K.C.

SIR WILLIAM BEALE died at Dorking while on a visit to friends, on Thursday April 13, at the ripe age of eighty-two, in full possession of his faculties. His remains were cremated at Golders-green on April 19; a service in his memory was held in Lincoln's Inn Chapel on April 26. His qualities had endeared him to a wide circle of intimates, in scientific, legal and political society, by whom his loss will be deeply mourned.

Beale's early training was that of a chemist, the intention being that he should enter an ironworks at Rotherham in which his family was interested. He made a beginning in the laboratory of Mr. Hill, a well-known consulting chemist in Birmingham; he then studied in Heidelberg and Freiberg, finally in Paris. At Heidelberg he was brought into contact with a number of chemists who afterwards became well-known—Matthiesen, Mond, Roscoe, Russell and others.

After but a short stay in the ironworks, Beale turned his attention to the law as offering better prospects; he entered Lincoln's Inn in 1867. Throughout his life, however, he retained his scientific interests and long acted as honorary legal adviser to the Chemical Society. He was one of the most popular and active members of the now defunct B club, a club of chemists whose doings have been chronicled by Dr. A. Scott in one of his Presidential addresses to the Chemical Society. At Freiberg Beale became interested in mineralogy and crystallography. When, in later years, the subject was developed and he desired to modernise his knowledge, I was able to hand him over to William Pope, then active as demonstrator of crystallography in my department at the Central Technical College; they contracted a firm friendship. Later on Beale even wrote a treatise on the subject, in which he put forward an original graphic method of presenting the facts of crystal symmetry. He was many years Treasurer and finally President of the Mineralogical Society. He also took an active interest in the Royal Institution.

Beale entered Parliament, after several ineffective attempts at Birmingham, as Liberal member for South Ayrshire, in 1906, retaining his seat until he resigned in 1918. He enjoyed a high reputation in legal and political circles, on account of the breadth and accuracy of his knowledge and his wonderfully balanced sane judgment. Of late years he spent much of his time, always surrounded by friends, at his Scotch home, near Barrhill in Ayrshire, most beautifully placed on an open grouse moor in sight of the Galloway Cauldron, Merrick, the highest peak in South Scotland, being a prominent feature in the view. Geikie's "The Ancient Volcanoes of Great Britain" was not infrequently taken down from his shelves. H. E. A.

SIR A. P. GOULD.

SIR ALFRED PEARCE GOULD, whose death at the age of seventy years we announced last week, had been a member of the honorary staff of the Middlesex Hospital since 1882, and was a consulting surgeon at the time of his death. He was a Fellow of the Royal College of Surgeons and a Master of Surgery at the University of London, of which he was Dean of the Faculty of Medicine 1912–16, and Vice-Chancellor 1916–17. His publications include the "Elements of Surgical Diagnosis," which went into five editions, and the Bradshaw Lecture on Cancer (1910). He was joint author of the "International Text-Book of Surgery." Though a surgeon of wide interests, Sir A. P. Gould devoted much work to the study of the clinical treatment of cancer, and was early in recognising the valuable

adjuncts which X-rays and radium were to prove in the treatment of malignant disease. At the Middlesex Hospital he acted for a number of years as chairman of the Cancer Investigation Committee, and thus held a watching brief for any new remedial agent likely to prove of benefit in the treatment of cancer. He was an excellent teacher and did not spare himself in the many services which he was asked to undertake. He was at some time president of the clinical section of the Royal Society of Medicine, of the Medical Society of London, and of the Röntgen Society. Throughout the period of the war he acted as Officer-in-Charge of the Surgical Division of the 3rd London General Hospital at Wandsworth.

Current Topics and Events.

DR. E. H. GRIFFITHS, the General Treasurer of the British Association, informs us that Sir Charles Parsons has conveyed to the Trustees of the Association a gift of ten thousand pounds 5 per cent. War Loan Stock, which he has placed unreservedly at the disposal of the Council. This generous gift comes at a very opportune time, as the finances of the Association have suffered depletion during the past seven years, and there was a danger that the activities of an association which has rendered such notable services to science in the past might suffer restriction. It is interesting to note that the total sum granted in aid of research by the Association, since its foundation in 1831, exceeds 83,000*l*.

THE Mount Everest Expedition, with the exception of Messrs. Finch and Crawford, who are delayed by the transport of the oxygen apparatus, arrived at Khampa Dzong on April 11. General Bruce's despatch to the *Times* describes the march from Phari Dzong. Considerable difficulty was experienced in obtaining a sufficiency of transport animals. The Tibetan authorities did their best, but owing to the earliness of the season many of the animals were in very poor condition. The expedition travelled in two divisions and found the march very trying. On the Dongka pass, where ridges of 17,000 ft. had to be crossed, low temperatures were experienced, but fortunately the blizzard experienced on the previous day had ceased. All members of the expedition are in good health, the trying experiences having affected neither the white men nor the hillmen.

THE Bessemer Gold Medal of the Iron and Steel Institute for the year 1921 has been awarded to Mr. Charles Fremont, in recognition of his services in the advancement of the metallurgy of iron and steel and the technology of the testing materials. The following grants from the Andrew Carnegie Research Fund were made during the year by the council of the Institute: 100*l*. to Dr. L. Aitchison, Birmingham, for the investigation of the low apparent elastic limit in quenched and work-hardened steels, with particular reference to fatigue strength, proof stress, and constitution; 100*l*. to Prof. C. O. Bannister and Mr. A. E. Findley, Liverpool, for the investigation of the mechanical properties and heat treatment of very low carbon high chromium steels; 100*l*. to Mr. F. C. Langenberg, of Watertown Arsenal, United States, for research on impact testing; and 50*l*. to Mr. J. N. Greenwood, Sheffield, for research in optical data of steels and steel-making materials necessary for correcting temperature measurements of molten steel taken with an optical pyrometer.

THE Third Hurter and Driffield Memorial lecture of the Royal Photographic Society is to be delivered at the Royal Society of Arts, at 8 o'clock, on Tuesday, May 9, by Prof. The. Svedberg, who will take as his subject "The Interpretation of Light Sensitivity in Photography."

AT the annual general meeting of the Manchester Literary and Philosophical Society held on April 25, the following officers and members of council were elected:—*President:* Mr. T. A. Coward; *Vice-Presidents:* Sir Henry A. Miers, Mr. W. Henry Todd, Prof. Arthur Lapworth, and Mr. C. E. Stromeyer; *Hon. Secretaries:* Dr. H. F. Coward and Prof. T. H. Pear; *Hon. Treasurer:* Mr. R. H. Clayton; *Hon. Librarians:* Mr. C. L. Barnes and Dr. Wilfrid Robinson; *Hon. Curator:* Prof. W. W. Haldane Gee; *Members of Council:* Dr. W. M. Tattersall, Prof. F. E. Weiss, Mr. Francis Jones, Miss Laura Start, Prof. S. Chapman, Prof. W. L. Bragg, the Rev. A. L. Cortie, Mr. R. L. Taylor, and Mr. William Thomson.

A PROVISIONAL programme has been issued of the annual general meeting of the Society of Chemical Industry to be held in Glasgow on July 4-11 next. On the first day of the meeting, formal business will be discussed and Dr. R. F. Ruttan will deliver his presidential address. During the morning of July 5, Prof. H. E. Armstrong will give the Messel Memorial lecture, while on the following day a novel feature will be introduced in the form of a demonstration of kinematograph films showing the manufacture of rubber, the production of sulphur, and the preparation of paper from wood. The Chemical Engineering Group of the Society will hold two sessions on July 6, at which papers on the design of ammoniacal liquor stills, tar and glycerine distillation, and the general problem of evaporation will be read. Visits to various works, among which are the Nobel Industries, Ltd., and several excursions, will occupy the remaining portions of the meeting.

AT the fifth annual general meeting of the Society of Glass Technology held on April 26, Prof. W. E. S. Turner was elected president. In his presidential address entitled "The British Glass Industry: its

Development and Outlook," Prof. Turner gave an account of the growth of the British glass industry from the time of the Roman occupation onward. Speaking generally, there was a steady growth up to the year 1875, after which time the number of glass factories began to decrease and the imports of finished glassware increased. This steady decline was arrested on the outbreak of war in 1914, and during the last few months of 1914 and 1915 the industry was revived. New branches were created under the stress of war for the production of chemical glassware and for lampworking. They grew to such an extent that during the last twelve months of the war period more than two million pieces of chemical glassware were made at the furnace, and some 39 million lampblown articles and more than a million pounds of glass rod and tubing were manufactured. The output of electric lamp bulbs exceeded 43 millions, as compared with four million bulbs of pre-war years. Turning to the future, Prof. Turner acknowledged that the immediate outlook was not cheerful, but claimed that the industry was much more efficiently equipped than at any other time in its history.

We have received a communication, dated March 23, from Mr. Y. Venkataramaiah, Calcutta, in which he states that the plastic sulphur separating in the action of concentrated nitric acid on a crystal of sodium thiosulphate, which is ordinarily yellow, becomes distinctly green if a little colloidal gold or platinum solution is added to the acid before the addition of the thiosulphate. Sometimes small blue spots are visible on the separated sulphur. Colloidal gold appears to be more effective than colloidal platinum. The sulphur dissolves in carbon disulphide forming a light greenish solution; when treated with absolute alcohol it becomes yellow. It dissolves in hot methyl salicylate, and nacreous sulphur separates on cooling.

In a lecture delivered to the Société de Chemie Physique in February 1921, M. Edmond Bauer gave an excellent account of the present state of atomic physics, and the lecture has now been published by the society, in a pamphlet of about 50 pages entitled "La Théorie de Bohr, la Constitution de l'Atome et la Classification périodique des Éléments." It starts with the various atomic models, contrasting the rival merits of the static and the dynamic. There is then a description of the work on atomic numbers, both that originating with the X-ray work of Moseley, and that from Rutherford's theory and the work on the collisions of α-particles, and there follows a discussion of the periodic table. Next comes the photo-electric effect, and this is followed in due course by Bohr's theory. The lecture ends with a short reference to Born's work on the dynamics of crystals. It is remarkable how large a field the author has managed to cover in so small a space, and the whole is a very good sketch of the present condition of physical theory.

Dr. P. D. Strachan, Serowe, Bechuanaland Protectorate, S. Africa, writes to us stating that in his experience it is necessary to tune the octaves of the upper register of the piano sharp in order that the notes may not sound dull and flat. Professional tuners apparently do the same, giving as their reason that it adds brilliancy to the tone. Dr. R. S. Clay informs us that tuners regularly make the upper eight or ten of a piano a trifle sharp, but there is a difference of a few vibrations only from the true frequency. He suggests that there may be a physiological explanation, or it may be due to the fact that the overtones of the upper notes of a piano are sharp and so produce a desire for corresponding sharpness in notes sounded with them. The effect would become marked with high notes, for the ratio of the restoring force due to the stiffness of the wire becomes progressively important as the length of the vibrating segment becomes shorter. In other instruments, such as the flute, in the use of which Dr. Strachan states he has had a similar experience, it is suggested that the effect may be due to variations in the pitch caused by changes in the method of blowing.

The City Sale and Exchange, of 54 Lime Street, E.C.3, are issuing gratis and post free a catalogue of hand cameras that includes a very large number of items, and apparently every variety of pattern and price. It is gratifying to know that the prices have been very considerably reduced.

Our Astronomical Column.

Total Eclipse of the Sun.—The Lick Observatory has arranged an expedition to Wallal, on the northwest coast of Western Australia, to view the total solar eclipse of September 21. The station offers uniquely favourable meteorological conditions combined with a duration of totality of 5 mins. 18 secs. Various spectroscopic observations will be undertaken, and special cameras are being constructed for investigating the Einstein displacements of the stars. The members of the expedition are Prof. and Mrs. Campbell with Drs. J. H. Moore and R. J. Trumpler (of the Lick Observatory), Prof. A. D. Ross (of the Western Australian Observatory), Dr. and Mrs. Adams (of the Wellington Observatory), and Mr. J. B. O. Hosking (of the Melbourne Observatory). The party will be the guests of the Australian Commonwealth Government during their visit. Wallal will also be occupied by a party organised by Prof. C. A. Chant of Toronto, while Australian expeditions will view the eclipse from Goodiwindi in Queensland and from the north-east corner of South Australia.

Jupiter and his Markings.—Mr. W. F. Denning writes that a number of interesting observations of

features on Jupiter have been obtained recently by Mr. Frank Sargent at the University Observatory, Durham. The Red Spot Hollow was observed in transit across the central meridian on various dates and its longitude determined as follows: 1921, Dec. 12 = 260°·9, Dec. 22 = 259°·7, 1922, Feb. 21 = 257°·4, March 10 = 256°·0, March 31 = 256°·1, April 10 = 254°·2. These positions show a slowly decreasing longitude equivalent to a rotation period of 9 h. 55 m. 38·4 s. This is a decidedly lower rate than the spot exhibited about four years ago when the period was 9 h. 55 m. 34 s. The south tropical disturbance, which is now about 140° long, was central on April 6 in longitude 46° so that it follows the Red Spot Hollow by about 152°. Its rate of rotation during the present year has been about 9 h. 55 m. 32 s. or 6 seconds less than that of the Red Spot Hollow. In 1901 the difference of rotational velocity in the two objects amounted to 22s. but since that time the motions have been gradually approaching uniformity and may possibly in a few years become identical. Mr. Sargent has recently discovered a somewhat abnormal dark marking on the northern edge of the southern equatorial belt, and finds its rotation period to be 9 h. 51 m. 6 s. from 27 rotations performed from March 31 to April 11. He is continuing to follow this and other interesting features with his 10½-inch reflecting telescope.

OBSERVATIONS OF VENUS.—*Pop. Ast.* of March contains a study of this planet by Mr. Alfred Rordame. He has observed it regularly for 20 years with apertures between 4 and 16 inches. In 1921 he took several photographs during daylight with a 9-inch Alvan Clark refractor. Some of these are reproduced, and show some indubitable spots, which are confirmed on more than one negative. Naturally the chief interest concerns the rotation period. He notes that at first he accepted Schiaparelli's value, but now he has come to think that a value near 24 hours is correct. As illustrating the difficulty of the observations, he notes that on less than fifty occasions has he seen definite markings, and on six only has a positive movement of the spots been observed. Some drawings showing this are reproduced. One pair, taken on October 8-9, 1916, tend to confirm De Vico's period of 23 h. 21 m.; Mr. Rordame thinks that those spectroscopic determinations which were made in daylight are liable to error, owing to the blending of the sky spectrum with that of the planet. He considers that the planet is normally covered with dense clouds, the height of which is probably very great.

The same number of *Pop. Ast.* contains a note by Prof. St. John on a photograph of the red end of the spectrum of Venus; the dispersion was so great that the telluric lines would have been separated from those due to Venus's atmosphere by the Doppler effect. No companions, however, were visible to the telluric oxygen bands; it is concluded that oxygen is practically absent from the upper atmosphere of Venus.

SOLAR RESEARCHES.—The February number (vol. 34, No. 197) of the Publications of the Astronomical Society of the Pacific contains several communications on solar work. The first is a general article on the sun by Ferdinand Ellerman. "The Zeeman Effect on the Sun" is the title of the next article by Adrian van Maanen, written and translated from the Dutch journal *Physica*, the October (1921) number of which was dedicated to Dr. Zeeman in recognition of his discovery, 25 years ago, of the separation of spectral lines in a magnetic field. This article is of great interest, summing up the fine work done at Mount Wilson after Hale's important discovery of magnetic fields in sun-spots. Hale himself contributes a note on "Invisible Sun-spots," this term designating the invisible stage of spots which are usually visible during the greater part of their existence. By means of the apparatus which he describes, Hale indicates the importance of making a systematic search for local magnetic fields which may betray the presence of incipient or dying spots. Seth B. Nicholson gives a summary of Mount Wilson magnetic observations of sun-spots for November and December last, and describes the scheme of classification underlying the tables he produces. Systematic observations of the magnetic polarities of sun-spots have been made daily with the 150-foot tower telescope since 1915, and preparations are being made to publish all this valuable new work in detail. Spot groups are divided into three classes and designated unipolar, bipolar, and complex, and some interesting facts about their appearances are given.

PROPOSED 50-FOOT REFLECTOR.—A somewhat wild scheme is said to be contemplated by Prof. Todd and Mr. McAfee. This is the construction of a 50-foot reflector of 1200 feet focus, by utilising a mine-shaft of this depth at Chauaral, Chile, in the Andes, in the locality where Mars will pass exactly overhead at the opposition of 1924. The reflector will consist of rotating mercury, and there must be considerable incredulity about the possibility of keeping this sufficiently free from tremors and eddies to give tolerable definition. The plan ascribed to Prof. Todd is to use a flat, which throws the image into a cave at the side of the shaft, where the camera would be put. But clearly, with such high magnification, the shortest practicable exposure would give a blurred image on a stationary plate. A much better plan would seem to be to put a girder across the mouth of the shaft, carrying a plate-holder or eyepiece which could be moved by clockwork at the appropriate speed (about 1 inch per second). This is known as the Schaeberle method in eclipse photography, and has given satisfactory results. Prof. Todd is well known for bold and striking experiments, and all will wish him well, though without much expectation of success.

A CATALOGUE OF DOUBLE STARS.—A Greenwich volume has lately been published containing the measures of double stars made with the 28-inch refractor between 1893 and 1919. Earlier observations are given for many stars, and in an exhaustive series of notes, mainly by Mr. Jackson, the character of the motion is discussed and the deviations from published orbits indicated. There are also 25 new orbits, computed by him, many of which deviate considerably from earlier determinations. Hypothetical parallaxes are deduced for all stars for which orbit elements are available, and also for other stars which have been observed over an arc sufficiently long to indicate the amount of curvature. The assumed mass of each pair is twice the solar mass; this assumption gives a solar velocity of 19 km./sec., which is in close accord with the spectroscopic value. Comparison of the hypothetical parallaxes with the spectroscopic ones shows perfect accord, in the main, in the case of orbit-stars, but in the arc-stars the hypothetical parallaxes exceed the spectroscopic by 30 per cent.; this is not an excessive error for such small parallaxes (0·07″ to 0·02″). There is some indication of mass varying with spectral type, but this has not been used in obtaining the results.

Research Items.

PREHISTORIC COOKING-PLACES IN NORFOLK.—At the recent annual meeting of the Prehistoric Society of East Anglia, the president, Miss N. Layard, well known for her archæological investigations, particularly in the neighbourhood of Ipswich, delivered an address on prehistoric cooking-places in Norfolk. In the park at Buckenham Tofts, the discovery of what seems to have been a tribal cooking-place was due to rabbits scratching to the surface a number of cracked and fire-marked flints. The term usually applied to such articles is "pot-boilers," but more probably the heated stones were dropped into water-filled troughs made of the skins of large animals, either suspended from poles or used to line pits in the ground. Water and meat are easily boiled in these circumstances by keeping up the supply of heated stones, and the result, as shown by experiments made by the lecturer, was a mixture of charcoal, dirt, and ashes, with well-boiled but discoloured meat.

AN EARLY IRON-AGE VILLAGE NEAR DEVIZES.—In the report of the Marlborough College Natural History Society for 1921, Mrs. Cunnington describes an Early Iron-Age village discovered by chance on All Cannings Cross Farm, about 6 miles east of Devizes. The chief interest and importance of the site lies in the fact that the pottery as a whole seems to belong to the Hallstatt period, and to be throughout of the Hallstatt type. The site seems to have been occupied for a comparatively short and definite period, perhaps for some three centuries. Not a single fragment of anything Roman has been found, so that the occupation seems to have ended well before the Roman conquest, perhaps even some centuries earlier. A full report of the excavations will be found in the *Antiquaries Journal*, January 1922.

MISSIONARIES AS ANTHROPOLOGISTS.—Sir James Frazer in his introductory lecture of a course on the Belief in Immortality and the Worship of the Dead in Polynesia, published in *Science Progress* for April, discusses the general principles of anthropological inquiry, and notes that missionaries, men of education and character, who usually live for years among people of the lower culture, learn their language, and gain their confidence, have special opportunities for observing and recording the habits of savage races. He refers in particular to *Anthropos*, edited by an Austrian priest, Father W. Schmidt, and composed mainly of articles contributed by Catholic missionaries in many parts of the world. "It is much to be desired that the various missionary societies of England would combine to produce a journal of the same scope and the same scientific character. Perhaps, in view of our sectarian differences, that is too much to hope for. But in any case it is highly satisfactory to know that our Protestant missionaries are awakening more and more to the importance of anthropology in the training of missionaries and are taking active steps to remedy what till lately was a most serious defect in their mental equipment."

A HUMAN CRANIUM DREDGED FROM THE RIVER TRENT.—In the March issue of the *Journal of the Royal Anthropological Institute* (vol. li.) Prof. L. Gladstone describes a human cranium which was dredged from the bed of the river Trent, near Hatfield, in 1916. It differs considerably from the average type of skull found in recent and medieval burial-grounds in England, and from the average living types. The circumstances of its discovery indicate that it has affinities with the type of skull found in round barrows associated with bronze implements and pottery of the Beaker class. This race is believed to have made their appearance on our eastern and southern coasts about 2000 B.C., and these large-headed, brachycephalic invaders mingled with the indigenous small and narrow-headed Neolithic population and with subsequent invaders, including the Romans and those from the adjoining European shores. "As a result of inter-marriage of individuals belonging to these races, we find descendants from the original stocks who possess the characters of either one or the other of the ancestral races, in a more or less modified form, or intermediate types." The mid-European or Alpine stock and the broad-headed people of south-west Norway are modern representatives of the Bronze-Age race, modified by intermixture, change of environment and conditions of life, the eating of soft food affecting their jaw form and facial type.

SELF-FERTILISATION IN MOLLUSCA.—In NATURE of January 5, p. 12, Mr. G. C. Robson directed attention to some records of self-fertilisation in Gastropod mollusca and pointed out their importance. Stress was laid in the letter on the desirability of further investigation of this phenomenon. We have lately received an apparently unpublished communication from Mr. S. Manavala Ramanujam, of the Zoological Department, Madras Christian College, in which he describes what appears to be a structural adaptation for self-fertilisation in a family of Pulmonate Gastropoda. In the Vaginulidæ a connection is found between the vas deferens and the receptaculum seminis in the same animal. This connection (the "canalis receptaculo-deferentinus" of Keller) has been described by previous authors (Keller, Pelseneer), but, so far as can be ascertained, without comment. Mr. Ramanujam does not advance any objective evidence that self-fertilisation is effected through this canal, but he is probably right in suggesting that it is used to conduct the animal's own sperm to the receptaculum seminis, if it should fail to receive a supply from another individual. The existence of this connection perhaps indicates that self-fertilisation is of common occurrence in the family.

THE DIRECTION OF THE FIRST MOVEMENT IN AN EARTHQUAKE.—It has been known for some years that the first impulse in an earthquake may appear as a rarefaction at one station and as a condensation at another. Mr. S. Nakamura (*Journ. Meteor. Soc.*, Japan, February 1922) has studied recently several examples of such variations in Japan. In an earthquake at Miyosi (near Hiroshima) the disturbed area was divided into four quadrants by two slightly curved lines. In the south-east quadrant the direction of the first movement was inwards, and in the north-east and south-west quadrants outwards, the remaining quadrant being occupied mostly by the sea. In the Tokio earthquake of December 8, 1921, the distribution was somewhat similar, the curved bounding lines, however, being not quite at right angles; in two opposite regions (north-east and south-west) the movement was inwards, in the other two regions outwards. The great Chinese earthquake of December 16, 1920, seems also to belong to this type, the impulse being outwards in Formosa and inwards in Japan and at Zi-ka-wei. A second type was

illustrated by an earthquake near Oomati (Shinano), in which the first movement was inwards on the south-eastern side of the epicentre and outwards on the north-western side. There appears also to be a third type, though not yet well established, in which the first movement is mainly inwards in all directions from the epicentre.

The Earth's Interior.—The planetesimal hypothesis of the aggregation of the earth is now so justly associated with the name of T. C. Chamberlin that his "Study of fundamental problems of Geology" (Carnegie Institution of Washington, 15th Ann. Rep., p. 412, 1921) has a very wide interest. Continuing his arguments as to the structure and behaviour of a contracting globe formed of solid mineral aggregates, he remarks on the effects of pressure in generating silicates of high density even within the limits of the earth's outer layers. Without actually predicting the occurrence of still denser compounds, formed of familiar types of crustal molecules, towards the earth's interior, he states that "there seems no need to assume the presence of an amount of metal, or other intrinsically heavy material, greater than is implied by the planetary evidence already cited."

Tertiary Fossils of Burma.—Comparative diagnoses of Pleurotomidæ, and of Conidæ and Cancellariidæ from the Tertiary formations of Burma form two consecutive papers by E. Vredenburg in the Records of the Geological Survey of India, vol. 53, 1921, pp. 83-141, illustrated by four excellent photogravure plates by S. C. Mondel. These two papers are in continuation of a previous one on the Terebridæ, by the same author, that appeared in vol. 51, and consist mainly of descriptions of new species. One of these, *Mangilia* [sic] (*Clathurella*) *quinqueangularis*, it is claimed "does not resemble any previously described shell either fossil or recent." To the palæontologist this work will be invaluable, but the systematic conchologist will wish that the writings of later authors than Cossmann, whose big publication Vredenburg has evidently followed, had not been entirely ignored. Both Prof. Dall in America, and Iredale in this country, have advanced our knowledge of these groups since Cossmann dealt with them.

Oil Shale as a Source of Gasoline.—The Journal of the Franklin Institute for March 1922 contains a paper by Prof. R. H. McKee on Gasoline from Oil Shale, in which he outlines the processes of extraction of petroleum from shale, and the possibilities of developing a successful industry in the United States. The text of the paper is not new; as usual, the Scotch Shale Industry is described as a "type," and modifications of method and practice are suggested for the treatment of American raw material. The significance of the paper lies not so much in the principles it seeks to enunciate, but in the warning it contains regarding the gradual decline in production of natural oil in America, and the corresponding need for activity in development of the oil-shale resources of that country. The importation of petroleum from Mexico into the United States, for example, increases annually, in order to help meet the demand both for motor spirit and for petroleum products; as Mexico is regarded by many (and evidently by the author) as a short-lived field, the position in America is likely to become critical within the next decade. Sooner or later a drastic scheme of conservation of the oil resources of the United States for national requirements must eventuate, and before this happens the oil-shale industry and the utilisation of other material as a source of fuel, must be well established in that country. It is well known that there are many technical difficulties arising in connection with the extraction of oil from shale, and that the methods employed in Scotland are not suited to all kinds of shale, especially some of the western American varieties. It is to the solution of these difficulties that American experts are now turning their attention, and research is being assiduously carried on in the Chemical Engineering Department of Columbia University, New York City, under the author's direction, with the view of studying the fundamental factors on which the industry must be based. Similar work is also in progress at the Colorado School of Mines, under the direction of Dr. V. C. Alderson, the well-known authority on oil shale.

Agriculture in India.—The thirty-sixth issue of the Agricultural Statistics of India, for 1919–1920, sets forth most comprehensively the details relative to the position of agricultural affairs. The rainfall on the whole was normal or excessive, no deficit being reported for any area. Following on a marked depression in 1918–1919, the period under review shows a general recovery, though the high-water mark of 1916–1918 was not reached. The area sown was 255 million acres, of which 211 millions were under food crops and 44 millions under others. A considerable increase in the area sown occurred in the North-west and West and in Burma, which more than counterbalanced a drop in the Central Provinces and Bengal. There was less variation in the acreage of rice, cotton, and jute than in other crops, no less than 79 million acres being under rice. While the majority of crops are distributed more or less throughout the country, the larger part of sugar-cane and wheat is grown in the Punjab and United Provinces, tea in Assam, and practically the whole of the jute in Bengal. During the past ten years an increase of 18 millions in livestock has been recorded, due entirely to the larger number of bovine animals reared. In the appendix to the report a useful list of crops is given, with both vernacular and botanical names.

Meteorology in the Netherland Indies.—A general summary of "The Climate of the Netherland Indies" is given by Dr. C. Braak—Verhandelingen, No. 8, vol. i., parts 1 and 2. A short English summary is given with each part. The most prominent feature of the climate is said to be its monotony or its uniformity from day to day, for the moving low-pressure systems common to the higher latitudes which make the weather variable are practically unknown. The most important weather changes are the variations of rainfall, and the monsoons cause a yearly variation in the climate which is rather small in the north but considerable in the south. It is stated that the Malay Archipelago is the most typical monsoon region of the world, the trade-wind systems being disturbed by the influence of the continents of Asia and Australia. Pilot balloon observations at Batavia show that the west monsoon from December to April reaches on an average to a height of 5000 m., whilst from May to October easterly winds blow at all levels up to 7 km. The monsoon wind on high mountain tops is stronger at night than during the day. Near the coast the land and sea breezes are said to have a strong influence. Monthly charts are given of the isobars and winds over the Archipelago which show a complete reversal of meteorological conditions during the year with the change of the monsoon.

Sheep-Breeding and Ancestry.[1]

In the report referred to below, Prof. Ewart first briefly reviews the facts and beliefs about sheep, and, under nine concise statements, summarises our knowledge of the origin and development of present-day types. Much of the work upon which this summary is based is attributable directly to the extensive researches, extending over many years, which Prof. Ewart himself has conducted. In Figs. 1 and 2 the results of these researches are represented diagrammatically.

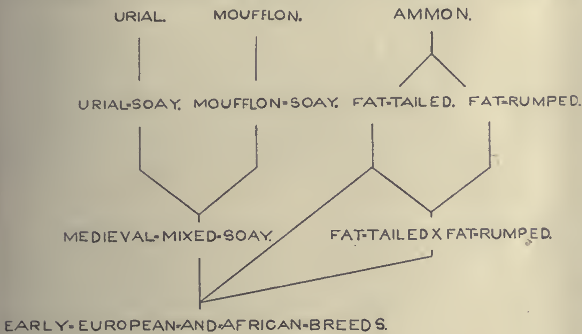

Fig. 1.

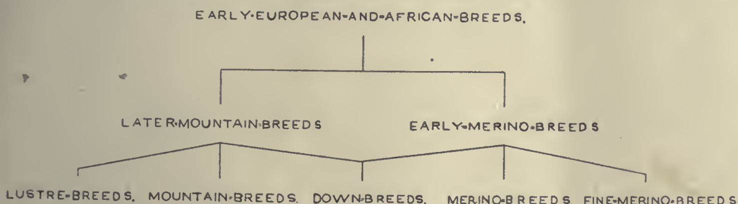

Fig. 2.

From Fig. 1 it will be gathered that the primitive sheep of Europe was of the Soay type, this type having a double ancestry in the Urial or horned sheep and the Moufflon or hornless sheep. Both these types are in evidence to-day in Soay flocks and both are still short-tailed. Nevertheless, both these types cross freely with long-tailed sheep. The modern sheep would seem to have obtained both its tail and its fattening characteristics through the fat-tailed and fat-rumped sheep of Asia. It is further conceivable that the Soay × Fat-tailed or Soay × Fat-rumped sheep followed two lines of migration across Europe—one to the north, coming eventually into the British Isles through the kingdom of Scandinavia, and the other along the shores of the Mediterranean, developing eventually into the Merino sheep of Spain, and in this form taking part in the formation of the British "Down" breeds. In Fig. 2 this latter suggestion is illustrated diagrammatically and the ancestry of present-day sheep indicated.

Fig. 3.

Fig. 4.

There is still a "drift" southwards of sheep from Scotland and a "drift" northwards of sheep from the south of England. It may be that these two drifts are a relic of the drifts of the Nordic and Mediterranean races across the British Isles; but such a theory would need many more facts than are at present available to support it. There is, however, direct support for Prof. Ewart's suggestion respecting our present-day sheep having a fat-tailed ancestor. In Fig. 4 is illustrated the normal head and ears of the Suffolk Down type of sheep. In Fig. 3 is given a photograph of a lamb discovered among a number of this year's Suffolk lambs; and in Fig. 5 an illustration of a sheep with the fat-tailed head. The similarity is very striking. Further, the suggestion that at the base of English Down breed is the Merino is illustrated

Fig. 5.—Head of a 21-days'-old extracted Fat-tail ram lamb. From the *Scottish Journal of Agriculture*. By permission of the Board of Agriculture for Scotland.

in Fig. 4, a Suffolk Down lamb with "crinkled skin"—this crinkled skin being very characteristic of sheep of the Merino type. In further support

[1] Report on Sheep-breeding Experiments. By Prof. J. Cossar Ewart. British Research Association for the Woollen and Worsted Industries, Torridon, Headingley, Leeds.

of the fat-tailed ancestry of present-day sheep, Prof. Ewart noted some time ago a Border-Leicester sheep with the tip of the tail turned up following the lines of the tail of the fat-tailed sheep. Thus it would appear that the nine brief statements with which the report starts are of quite extraordinary interest, and in addition may usefully be kept in mind when studying present-day types of sheep.

Mendelian principles—particularly involving the reshuffling of "characters"—are then insisted on and the value of crosses beyond the first cross emphasised. This is really essential, as so many breeders fail to realise the importance of the F_2 cross. Australian sheep-breeders, however, say "three generations to obtain the cross and thirty to fix it"!

The report is then divided into two sections: (1) experiments with Highland blackface and other modern breeds; and (2) experiments with primitive breeds. It is pleasing to note the assistance accorded by the Duke of Richmond and Gordon and his agent, Mr. R. A. Dawson, Mr. R. Macmillan, Captain J. Stirling, Mr. Dyson Perrin, Sir John Ramsden, Sir Malcolm Macgregor, Mr. Gordon, and the veteran of experimental sheep-breeders, Mr. J. Elwes of Colesborne, Cheltenham.

The Scottish Board of Agriculture is also taking a deep and broad interest in experiments here partially recorded. Ten photographs of typical sheep and their crosses add materially to the value of the report.

The report concludes with references to the experiments in progress under the direction of Prof. White in Wales and to the experiments on British wool characteristics at present being carried out at the University of Leeds. A. F. B.

The Organisation of Knowledge.

CURIOUS reflections on the present state of scientific knowledge are suggested by the extraordinarily interesting address of Dr. F. L. Hoffman to the social and economic science section of the American Association, at the Toronto meeting last December, on "The Organisation of Knowledge," published in *Science* of March 10 and 17. Dr. Hoffman has been for thirty years a very practical organiser of knowledge in connection with his management of the Prudential Insurance Company of America. He has been reading Prof. Whitehead's "The Organisation of Thought," and it seems to have impressed him with a sense of the remoteness of mathematical principles, mathematical methods, and mathematical research from any organisation of science which is serviceable in practical life.

The problem Dr. Hoffman deals with is a profound one, and carries us back to the old distinction between truths of reason and matters of fact which in some form has been the problem of modern philosophy since it first arose with Bacon and Descartes. It is interesting to look back on the confidence with which some of the leaders of philosophic thought in the nineteenth century supposed they had solved it. The confidence appears first in Comte and afterwards in Spencer, who devoted a great part of his intellectual energy to an attempt to give it practical effect. It rested on the idea of a division of labour. It was to be the business of scientific workers to observe and collect facts, guided of course by certain rules of classification and arrangement, but it was to be the special business of philosophers to systematise and generalise. An amusing illustration is a story related to the present writer many years ago by the late Dr. Williamson, professor of chemistry in University College. Herbert Spencer had written to him to ask him whether certain specified chemical experiments could be relied on as correct. In his reply he added to the information asked for his own interpretation, only to receive by return a sharp rebuke pointing out to him that his business was to observe and report facts; it was for the philosopher to theorise concerning them. It is perhaps needless to add that the narrator saw no humour in the story.

The fact gatherer, Dr. Hoffman tells us, should be the fact user. It is the reason he gives for this, however, that deserves particular attention. Fact gathering is impossible without imagination, and imagination is what the mathematician is ever trying to get rid of. The ideal of science is forecasting, and in the business of insurance we have the most complete development of it. In the organisation of knowledge for insurance the whole principle is that all facts are regarded in their interrelation or interdependence for useful purposes. Dr. Hoffman contrasts this with Prof. Whitehead's appeal for a first-hand knowledge which has "never been scared by facts." Progress and discovery depend upon a disciplined imagination, and Dr. Hoffman quotes Karl Pearson, "the man with no imagination may collect facts, he cannot make great discoveries." What we want to forecast are the sort of things mathematics is helpless before, things like the international war, or the influenza epidemic.

Dr. Hoffman concludes his address by outlining the general scheme of his own organisation of the library and information service of his business office.

The Centenary of Naval Engineering.

UNDER this title an interesting paper was read at a meeting of the Newcomen Society on March 30 by Engineer-Commander Edgar C. Smith. Among other matters treated was the development of paddle-wheel vessels, and a notable feature is presented by two tables giving particulars of steam vessels added to H.M. Navy during the period 1820-1850.

During the first twenty years all Navy boilers were of the flue type and were box-shaped. Leakage was very frequent; Dinnen remarks on the numerous "weeps" of which no notice was taken. These boilers were suitable for low pressures only, and it was forty years before the working pressure increased from 3·5 to 20 lb. per sq. in.

Great care was necessary for working these early boilers with salt water. Ships at sea put out the fires every third or fourth day and emptied the boiler. Afterwards, blowing down every two hours became the rule. If the blow-down cocks jammed, the water could be blown through the hand pump, or, according to Murray, "a usual plan is to knock out a rivet from the bottom of the boiler." Feed heating came into use early, an annular tank being placed round the funnel.

The first vessel in the Navy to have a surface condenser was the *Megaera*. She had the five-fold combination of an air-pump, a circulating pump, a surface condenser, an evaporator, and a steam saver. This vessel was wrecked in 1843. The oscillating engine was invented by Murdock, improved by Manby, taken up by Maudslay, and its final success was due to Penn. Since all warships had to retain their sailing qualities, special attention had to be paid to devices for preventing interference from the paddle-wheels whilst the vessel was under sail.

We are indebted to the *Engineer* for the foregoing details, and trust that the author will complete his work by another paper dealing with the development of screw propulsion.

British Research Chemicals.

WE have received a pamphlet entitled "British Research Chemicals produced by Members of the Association," issued by the Association of British Chemical Manufacturers. This is a revised edition of the association's earlier pamphlet, and now contains inorganic as well as organic chemicals. In the list of inorganic chemicals, however, there are many which cannot fairly be called research chemicals, and can be obtained from almost any dealer. These include alum, ammonium chloride, barium chloride, bismuth subnitrate, and the like. It is evident that the Association had research chemicals in mind in drawing up the list, since such substances as ferrous ammonium sulphate are omitted. This inclusion of common chemicals swells the bulk of the list without adding to its value.

Although the preface states that there are certain chemicals on the list a permanent supply of which cannot be guaranteed unless there is sufficient demand (these might have been indicated in some way), it is evident that considerable progress has been made since the issue of the first edition, and the manufacturers are to be congratulated heartily on their efforts to supply from home sources materials which were obtained formerly from abroad. The list is far from complete; the present writer sought in vain for four not very rare substances he requires for research and used to obtain from Germany. With such an excellent beginning, however, the by no means small difficulties of research workers at the present time should rapidly be alleviated.

We notice that the manufacture of new chemicals may be undertaken by one or other of the firms "according to demand." We wish to point out, however, that this will scarcely meet the case satisfactorily. There are some materials which could formerly be obtained from German firms for which the demand must have been extremely small. If the research worker is to be told that the materials he requires cannot be made in this country because there do not happen to be a hundred other people working on the same subject, he will not derive much comfort from the statement. We offer these criticisms in the hope that they may be of assistance, and not in any way as detracting from the praise which is due to the firms for what they have already accomplished.

University and Educational Intelligence.

LEEDS.—At a meeting of the Court of the University of Leeds, held on April 26, it was decided to confer the following honorary degrees among others: *D.Sc.*, Sir Dugald Clerk; Sir Frank Dyson, Astronomer-Royal; Sir Richard Gregory; Sir Charles Sherrington, President of the Royal Society, Waynflete Professor of Physiology in the University of Oxford; and Sir Harold Stiles, President of the Association of Surgeons of Great Britain and Ireland, Professor of Clinical Surgery in the University of Edinburgh. *M.Sc.*, Mr. R. W. Haydon, until recently Lecturer in Agriculture in the University.

A CONFERENCE of representatives of the Universities of the United Kingdom will be held on May 13 in the Botanical Theatre, University College, London. The subjects and the openers of the discussions are as follows: the urgent need for the provision of enlarged opportunities for advanced study and research (Dr. J. C. Irvine); the increase of residential accommodation for undergraduate and other students (Sir Michael E. Sadler); specialisation in certain subjects of study by certain universities (Dr. L. R. Farnell); and the organisation of adult education as an integral part of the work of the universities (Sir. Henry A. Miers).

THE Melbourne correspondent of the *Times* announces that the Universities of Melbourne, Sydney, and Adelaide have agreed to invite Prof. Einstein, when he visits Java, to continue afterwards to Australia and visit the principal cities. Sydney and Melbourne will contribute 80*l.* each towards his expenses, and Adelaide 60*l.*

IT is announced in the *Chemist and Druggist* that under the will of the late Mr. Henry Musgrave sums amounting to 57,000*l.* have been bequeathed to Queen's University, Belfast. The Senate requested the Academic Council to make the consequential regulations for awarding "The Musgrave Research Studentship."

IN a new magazine, *The Beacon*, for April, Mr. E. H. Dance writes on "The Channels of Education: a Suggestion for Remuneration Economy." He admits that economy is as necessary in education as in other national activities, and he remarks that the Scripture lesson is the most unfruitful in the whole curriculum; he also states that the advantages of commandeering a large proportion of the time allotted to it and transferring it to geography would be incalculable. It is suggested that economics might largely take the place of Latin. Science teaching in its present form he condemns because its matter is of little real utility, "even when the canon of utility is educational . . . in spite of recent developments, education continues to lay undue emphasis on deductive reasoning." Science teaching, as now carried out, might, he thinks, be replaced by a more suitable medium: "that medium lies ready to hand in the modern treatment of history. History may be described as the laboratory of politics." "The inculcation of a general æsthetic sense is perhaps the most obvious need of modern education." Some of us may find it difficult to accept the writer's conclusions, but the article is well written and suggestive.

IN the course of his presidential address, delivered on April 20 at the annual general meeting of the Institution of Mining and Metallurgy, Mr. S. J. Speak referred to the part which the Institution has played in the development of technical education. Speaking of the Imperial College of Science and Technology, London, and particularly of the Royal School of Mines, he said that the Institution had aimed always at securing recognition for the College as "the technological centre of the Empire." The work of the College was, however, hampered seriously by lack of the power to grant degrees, and for this reason it is advocated that the status of the College should be raised to that of an Imperial University of Science and Technology. Opposition to this suggestion comes mainly from two sources: first, from the University of London, which naturally desires to absorb vigorous local institutions into itself and fails to see that facilities for obtaining London degrees do not meet the case. The second source of opposition is found in those educated on the classical side of existing universities, and to them a University of Science and Technology is unthinkable. Mr. Speak protested against this as suggesting that the study of the "humanities" is a higher form of education than the study of science.

Calendar of Industrial Pioneers.

May 4, 1879. William Froude died.—" The greatest of experimenters and investigators in hydrodynamics," Froude began his researches on the motion of ships among waves in 1856. They were made at the request of I. K. Brunel, who was then engaged with the building of the *Great Eastern*. Froude had been employed under Brunel on the Great Western Railway. His work led to the construction by the Admiralty of the experimental tank at Torquay, the first of its kind ever built. He carried out experiments on the effects of bilge keels and on the resistance and propulsion of ships, and he is also known as the inventor of a dynamometer.

May 4, 1886. James Muspratt died.—After an adventurous youth, a part of which was spent in the Navy, Muspratt settled in Liverpool and began the manufacture of soda according to the Leblanc process. Six years later he was joined by Gamble and new works were erected at St. Helens. Afterwards he had works at Widnes and Flint. He has been called the father of the alkali trade in Lancashire. He was a great friend of Liebig.

May 4, 1908. Gustav Friedrich Herman Wedding died.—A distinguished writer on metallurgy, Wedding studied at the Mining Academies of Berlin and Freiburg and ultimately became professor of metallurgy at the Technical High School at Charlottenburg. His works were regarded as of exceptional value and in 1896 he was awarded the Bessemer Medal of the Iron and Steel Institute.

May 5, 1909. Bindon Blood Stoney died.—For many years chief engineer to the Dublin port authority, Stoney attracted attention by his use of huge concrete monoliths of 350 tons weight. He made an elaborate study of stresses in girders, contributed many papers to the scientific societies, and in 1871 was president of the Institution of Civil Engineers of Ireland.

May 6, 1897. Jedediah Strutt died.—A Derbyshire farmer, Strutt in 1758 and 1759, with his brother-in-law, took out successful patents in connection with stocking machines. He also suggested improvements in the spinning frame of Arkwright.

May 7, 1890. James Nasmyth died.—An eminent mechanical engineer and inventor, Nasmyth in 1829 became the personal assistant of Henry Maudslay, and four years later set up in Manchester as a maker of machine tools. To him we owe the steam hammer, the steam pile driver, the nut making machine, a hydraulic punching machine, and the coiled spiral wire flexible shaft now so largely used.

May 8, 1916. John Edson Sweet died.—The recipient of the John Fritz medal for his " achievements in machine design, and pioneer work in applying sound engineering principles to the construction and development of the high-speed steam engine," Sweet was at one time professor of mechanical engineering in Cornell University. To him was due the initial step leading to the founding of the American Society of Mechanical Engineers, of which he became the third president.

May 9, 1914. Paul Hérault died.—Born in 1862, Hérault studied at the Paris School of Mines and at the age of twenty-four brought out his electrolytic process for the production of aluminium, a discovery made independently in America by C. M. Hall (1863–1914).

May 10, 1864. Alphone René le Mire de Normandy died.—A pioneer in the modern practice of distilling fresh water from salt water, Normandy brought out his invention in 1851. A native of France, he became a practical chemist and settled in England in 1843.

E. C. S.

Societies and Academies.

LONDON.

Geological Society, April 12.—Prof. A. C. Seward, president.—F. W. **Edwards**: Oligocene mosquitoes in the British Museum, with a summary of our present knowledge concerning fossil Culicidae. All the specimens are from the Oligocene of the Isle of Wight. The genera appear to be inseparable from those of the present day, and some of the species suggest a fauna similar to that of Ethiopian and Oriental regions. No peculiar forms occur. The genus Anopheles has not been found, probably because of its comparative rarity. Three species from the Oligocene of the Isle of Wight, described by Prof. Cockerell, are referred to the genus Aedes; and two new species, one of Culex and one of Tæniorhynchus, are described. No fossil that can be positively referred to the Culicidæ is yet known from the Mesozoic.—A. C. **Seward**: On a collection of Carboniferous plants from Peru. The plants described were collected by Mr. J. A. Douglas in 1911 from coal-bearing strata on the south side of the Peninsula of Paracas, a few miles south of Pisco on the coast of Peru. They are mostly fragmentary; whether they are of an Upper or a Lower horizon is not certain. Hitherto no fossiliferous Palæozoic rocks have been recorded from the Peruvian coast.—Miss M. E. J. **Chandler**: The geological history of the genus Stratiotes: an account of the evolutionary changes which have occurred within the genus during the Tertiary and Quaternary eras. Stratiotes, a monotypic genus of European and West Asian water-plants, can be traced back to the Eocene. The recent seed was described and an account given of the modifications which have occurred in the genus since the Eocene period. Of nine species described, *S. aloides* alone is still living. Seven appear to be direct ancestors of the recent plant, while two perhaps represent a branch-line of evolution. The fossil species occur in great abundance, are widespread geographically, and each seems to have a limited range in time. They may therefore serve to correlate isolated freshwater deposits in Europe.

Royal Meteorological Society, April 19.—Dr. C. Chree, president, in the chair.—W. T. **Russell**: The relationship between rainfall and temperature as shown by the correlation coefficient. The temperature of any two successive months over a series of years is correlated to the extent of approximately $+0{\cdot}3$. Since the mean monthly temperatures for the twelve calendar months follow very closely a sine curve, the coefficient of correlation should be unity. Rainfall in alternate months shows some high correlation coefficients, *e.g.* the coefficient between the rainfall in June and August in London is $+0{\cdot}55$. There is a negative correlation of $0{\cdot}5$ between rainfall and temperature in the same month in summer—evidence of the effect of solar radiation—while positive coefficients are found for the winter months. The change is attributed to the influence of the ocean in maintaining a temperature in excess of that due to latitude and season.—R. A. **Fisher** and Winifred A. **Mackenzie**: The correlation of weekly rainfall. The weekly rainfall for the past forty years at York, Aberdeen, and Rothamsted has been examined with a view of exploring the main features of weather localisation. Probably simple laws connect these quantities over considerable areas, which will give an idea of the accuracy of meteorological estimates based on a limited number of stations. A well-marked annual periodicity in the rainfall correlations rises relatively slowly in the autumn, and the autumn

values commonly remain for about three months close to the mean value for the year.—S. **Chapman** and Miss E. **Falshaw**: The lunar atmospheric tide at Aberdeen, 1869–1919. Methods similar to those formerly employed for the Greenwich records were used. The phases of the tide at the two stations agree as well as can be expected considering that Aberdeen is more disturbed, and the amplitude appears to be slightly greater at Aberdeen than at Greenwich.

PARIS.

Academy of Sciences, April 3.—M. Emile Bertin in the chair.—The president announced the death of Prof. Ph. A. Guye, correspondent of the Academy for the section of chemistry.—A. **Lacroix**: A syenite containing corundum and sillimanite formed by endomorphism of granite.—M. **Hamy**: The determination of the diameter of stars by the interference method. The telescope objective is covered by a screen carrying two narrow slits, and if the latter are sufficiently near, Young's fringes are seen. When the distance between the slits increases, the fringes diminish in clearness and vanish at a distance which is a function of the diameter of the star. The formulæ for the determination of the star diameter are given, and the numerical constants worked out.—C. **Moureu** and A. **Lepape**: The estimation of krypton and xenon in absolute value by spectrophotometry. A simplification of the method described in 1911. Standard mixtures of pure krypton and xenon in argon have been prepared and the pressure determined, in the Plücker tube, at which the intensity of a given krypton (or xenon) line is equal to that of a fixed argon line. These pressures and proportions are given in two tables.—F. **Mesnil** and M. **Caullery**: The maxillary apparatus of *Histriobdella homari*; the affinities of the Histriobdellæ with the Eunicians.—M. René Baire was elected correspondent for the section of geometry in the place of the late M. Nœther.—N. E. **Nörlund**: The interpolation formula of Stirling.—B. **Gambier**: Isothermal surfaces with spherical isothermal representation.—J. **Le Roux**: The curvature of space.—S. **Millot**: Calculating balances. A plate oscillating on two knife edges and having various scales ruled on it perpendicular to the axis of oscillation can be used as a generalised calculating machine. A practical example of its use in a complicated calculation is given.—G. **Rémoundos**: Plane deformations and the problem of the thrust of earth.—M. **Frontard**: Law of the dangerous height of clay cuttings.—A. **Perot**: The measurement of pressure in the atmosphere of the sun. The method is based on the variation with pressure of the ratio of the wave lengths of two lines of the spectrum, the coefficients of variation with pressure of which are different. The present data are based on five iron lines and give a mean pressure of 34 cm. of mercury, or just under half an atmosphere.—J. **Mascart**: Observations of the partial eclipse of the sun of March 28, 1922, made at the Lyons Observatory (Saint-Genis-Laval). Observations of the times of contacts by six observers are given, and these differ appreciably from the calculated times given in the *Connaissance des Temps*.—E. **Esclangon**: Observations of the eclipse of the sun of March 28, 1922, made at the Observatory of Strasbourg.—T. **Moreux**: Observations of the eclipse of the sun of March 28, 1922. Observations made at Bourges under unfavourable conditions.—G. **Bruhat** and A. **Delaygue**: Determination of the upper point of inversion of the specific heat of the saturated vapour of benzine.—M. **de Broglie**: The corpuscular spectra of the elements. A continuation of previous researches carried out with larger apparatus. Reproductions are given of the spectra obtained with silver, tin, gold, and uranium.—C. **Gutton**: The simultaneous maintenance of an oscillating circuit and harmonic circuits.—P. **Job**: The hydrolysis of the roseocobaltic salts.—A. **Wahl**, G. **Normand**, and G. **Vermeylen**: The monochlortoluenes. Pure ortho- and para-monochlortoluenes were prepared and the melting point curve for mixtures of the two constructed. This curve can be used in the analysis of mixtures. In the chlorination of toluene, a new catalytic effect of lead chloride is noted, which has a bearing on the industrial preparation of benzyl chloride.—Mlle. G. **Cousin**: Tectonic observations of the secondary strata of the southern border of the Vosges.—L. **Dangeard** and Y. **Milon**: Contribution to the study of the Tertiary basin to the south of Rennes. Discovery of beds containing fishes and plants in the black clays at the summit of the Chattian.—P. **Bugnon**: The hypocotyl of the Mercurialis.—H. **Jumelle**: A great palm tree from the centre of Madagascar.—A. **Policard** and Juliana **Tritchkovitch**: The mechanism intervening in the fixation of fats by the cortico-suprarenal gland.—P. **Lecompte du Noüy**: The superficial equilibrium of the serum and of some colloidal solutions. A description of a new apparatus for studying the continuous variation of the surface tension of a liquid. With this it has been shown that, at constant temperature, the surface tension of solutions of sodium oleate, glycocholate and taurocholate, of saponin and of blood serum diminishes spontaneously with time, rapidly during the first ten minutes then more slowly, the results being expressed by an exponential curve.—E. **Roubaud**: The winter hibernation in the larvæ and nymphs of the flies.—E. **Grynfeltt**: The perforating fibres of the bone of mammals.—P. **Bouin**: The parallel conjugation of the chromosomes and the mechanism of the chromatic reduction.—H. **Bierry**, F. **Rathery**, and F. **Bordet**: Experimental azotemia and hyperproteidoglycemia.—E. **Burnet**: A type of arthritis frequently observed in guinea-pigs infected with *Micrococcus melitensis*.

CAPE TOWN.

Royal Society of South Africa, March 15.—Dr. J. D. F. Gilchrist, president, in the chair.—B. de C. **Marchand** and B. J. **Smit**: The soils of the Hartebeestpoort irrigation area (Pretoria and Rustenburg districts).—H. E. **Penrose**: The trend of radio-development. The various methods adopted for wireless transmission were described and compared with the three electrode thermionic valve method. The possibilities of transmitting a beam of wireless waves in any given direction and direction finding were also discussed.—W. S. H. **Cleghorne**: A study in charcoal: being a research on charcoals made from exotic woods grown in the Union of South Africa. Charcoals were classified by the following methods: (*a*) proximate analysis; (*b*) measurement of the fuel consumption per brake horse-power on suction gas engine trial at constant given load for six hours' run; (*c*) analysis of the gas from the gas producer while the engine was on the trial; (*d*) measurement of the weight of a given volume of charcoal. Charcoal from *Acacia saligna*, the common Port Jackson Wattle of the Cape Flats, gave excellent results.—F. G. **Cawston**: Some notes on the differentiation of closely-allied Schistosomes. Fresh-water snails are infested occasionally with the cercariæ of more than one species of trematode. There are conditions under which schistosomes may develop in other than their common intermediary host. A determination of the number of pairs of mucin glands is one of the best means of determining the species to which a cercaria belongs.

Official Publications Received.

Memoirs of the Department of Agriculture in India. Botanical Series, Vol. 11, No. 4: Studies in Gujurat Cottons. By Maganlal L. Patel. Part 1. Pp. ii+75-127+8 plates. 2 rupees; 2s. 6d. Botanical Series, Vol. 11, No. 6: The Influence of Atmospheric Conditions upon the Germination of Indian Barley. By W. Youngman. Pp. 145-151. 9 annas; 1s. (Calcutta: Thacker, Spink & Co.; London: W. Diary of Societies.

FRIDAY, May 5.

Iron and Steel Institute (at Institution of Civil Engineers), at 10.30 a.m.—D. Selby-Bigge: Recent Developments in Power Production.—A. Westgren and G. Phragmen: X-ray Studies on the Crystal Structure of Steel.—N. T. Belaiew: The Inner Structure of the Pearlite Grain.—J. H. Whiteley: Formation of Globular Pearlite.—A. F. Hallimond: Delayed Crystallisation in the Carbon Steels: the Formation of Pearlite, Troostite, and Martensite.—K. Honda: The Constitutional Diagram of the Iron-Carbon System, based on Recent Investigations.—K. Honda and T. Kikuta: The Stepped A1 Transformation in Carbon Steel during Rapid Cooling.—N. Yamada: The Heat of Transformation of Austenite to Martensite, and of Martensite to Pearlite.

Royal Society of Medicine (Laryngology Section), at 3.—Annual General Meeting and Special Clinical Meeting.

Royal Society of Arts (Dominions and Colonies and Indian Sections), at 4.30.—Prof. W. H. Eccles: Imperial Wireless Communication.

Royal Astronomical Society (Geophysical Discussion), at 5.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of Museum Specimens illustrating Umbilical and Diaphragmatic Hernia.

Institution of Electrical Engineers (London Students' Section), at 7.—R. P. Howgrave-Graham: Electrically Oscillatory Discharges.

Institution of Mechanical Engineers (Informal Meeting), at 7.—Failures.

Junior Institution of Engineers, at 8.—E. N. Ching: Casting under Steam Pressure.

Royal Institution of Great Britain, at 9.—Dr. M. Grabham: Biological Studies in Madeira

SATURDAY, May 6.

Association of Engineers-in-Chief (at St. Bride's Institute), at 7.30.—Discussion on Uniflow *v.* Multiple-Expansion Steam Engines.

MONDAY, May 8.

Royal Institution of Great Britain, at 5.—General Meeting.

Royal College of Surgeons of England, at 5.—Prof. Shattock: Demonstration of Museum Specimens illustrating Tuberculosis.

Royal Society of Medicine (War Section), at 5.30.—Annual General Meeting.

Royal Society of Arts, at 8.—F. F. Renwick: Modern Aspects of Photography (2) (Cobb Lectures).

Surveyors' Institution, at 8.—R. Cobb: Agricultural Valuations.

Royal Geographical Society (at Æolian Hall, 135 New Bond Street, W.1), at 8.30.—R. Bryce: The Klagenfurt Plebiscite.

Medical Society of London, at 9.—H. J. Waring: Annual Oration.

TUESDAY, May 9.

Royal Institution of Great Britain, at 3.—Sir Arthur Keith: Anthropological Problems of the British Empire. Series II. Racial Problems of Africa (3).

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—E. H. Cunningham Craig: The Oil Shale of Esthonia.

Zoological Society of London, at 5.30.

Royal Society of Medicine (Psychiatry Section), at 5.30.—Annual General Meeting.

Quekett Microscopical Club, at 7.30.—E. Cuzner: A Short Account of some Varieties of Marine Zoology.

Royal Photographic Society of Great Britain (at Royal Society of Arts), at 8.—Prof. The. Svedberg: The Interpretation of Light Sensitivity in Photography (Hunter and Driffield Memorial Lecture).

Royal Anthropological Institute, at 8.15.—Capt. M. W. Hilton Simpson: Some Ethnographical Researches among the Berbers of Algeria.

WEDNESDAY, May 10.

Royal College of Surgeons of England, at 5.—Prof. H. Burrows: The Results and Treatment of Gunshot Wounds of the Blood Vessels (1) (Hunterian Lectures).

Geological Society of London, at 5.30.—Prof. E. J. Garwood and Miss E. Goodyear: The Lower Carboniferous Succession in the Settle District and along the Line of the Craven Faults.—E. J. Wayland and Dr. A. Morley Davies: The Miocene of Ceylon.

Royal Society of Medicine (Surgery: Sub-section of Proctology), at 5.30.—Annual General Meeting.

Royal Society of Arts, at 8.—Major P. A. MacMahon: The Design of Repeating Patterns for Decorative Work.

Institution of Automobile Engineers (at Institution of Mechanical Engineers), at 8.—J. Watt: Automobile Calculations: Practical Methods for the Designer.

THURSDAY, May 11.

Royal Institution of Great Britain, at 3.—Prof. F. Keeble: Plant Sensitiveness. I. To Light.

Royal Society, at 4.—Election of Fellows, 4.30.—*Probable Papers.*—Lord Rayleigh: A Photographic Spectrum of the Aurora of May 13-15, 1921, and Laboratory Studies in connection with it.—Lord Rayleigh: A Study of the Presence or Absence of Nitrogen Bands in the Auroral Spectrum.—Dr. C. Chree: The 27-day Period (Interval) in Terrestrial Magnetism.—M. Barker: The Use of very small Pitot-tubes for measuring Wind Velocity.—E. T. Paris: Doubly-resonated Hot-wire Microphones.—Prof. J. C. McLennan and D. S. Ainslie: The Structure of the Line of Wavelength $\lambda=6708$ Å.U. of the Isotopes of Lithium.

Royal College of Surgeons of England, at 5.—Prof. H. Burrows: The Results and Treatment of Gunshot Wounds of the Blood Vessels (2) (Hunterian Lectures).

London Mathematical Society (at Royal Astronomical Society), at 5.—Prof. G. H. Hardy: The Elements of the Analytic Theory of Numbers (Lecture).—L. J. Mordell: The Integral Solutions of the Equation $y^2=ax^3+bx^2+cx+d$.—W. P. Milne: Sextactic Cones and Tritangent Planes of the same System of a Quadri-cubic Curve.—A. C. Dixon: An Integral Equation.—E. L. Ince: On Harmonic Equations and in particular the Equations associated with Parabolic and Circular Boundary Problems.

Optical Society (at Imperial College of Science and Technology), at 7.30.—Discussion on Motorcar Head-lights.

Royal Society of Medicine (Neurology Section), at 8.30.—Annual General Meeting.—Dr. E. Bramwell: Some Features of Myopathy.

FRIDAY, May 12.

Royal Astronomical Society, at 5.

Physical Society of London (at Imperial College of Science and Technology), at 5.

Royal Society of Medicine Clinical Section), at 5.30.—Annual General Meeting.

Malacological Society of London (at Linnean Society).

Royal Institution of Great Britain, at 9.—Dr. H. H. Dale: The Search for Specific Remedies.

SATURDAY, May 13.

Royal Institution of Great Britain, at 3.—Prof. O. W. Richardson: The Disappearing Gap between the X-ray and Ultra-violet Spectra. I. Grating Results.

PUBLIC LECTURES.

(A number in brackets indicates the number of a lecture in a series.)

FRIDAY, May 5.

University College, at 5.—Prof. T. Borenius: The Re-discovery of the Primitives (Admission by Invitation only);—at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (1).

King's College, at 5.30.—Dr. J. Hjort: Biological Aspects of Oceanography (4).—R. F. Young: The University of Prague.

TUESDAY, May 9.

University College, at 5.—Sir Arthur Shipley: Insects and Disease (2).

King's College, at 5.30.—Prof. H. Wildon Carr: The Principle and Method of Hegel (2). The Dialectic.

Gresham College, at 6.—A. R. Hinks: Astronomy (1) (Gresham Lectures).

WEDNESDAY, May 10.

University College, at 5.15.—Dr. D. H. Scott: The Early History of the Land Flora (3).

Gresham College, at 6.—A. R. Hinks: Astronomy (2) (Gresham Lectures).

THURSDAY, May 11.

St. Mary's Hospital (Institute of Pathology and Research), at 5.—Prof. G. Elliot Smith: The Anatomy of Anxiety.

Royal Society of Arts, at 5.15.—Sir Lawrence Weaver: Rural Re-Settlement and its Relation to Public Health (2) (Chadwick Lectures).

University College, at 5.15.—Sir Joseph J. Thomson: Atoms, Molecules, and Chemistry (2);—at 5.30.—H. E. Goad: Nature in Glosue Carducci's Poems.

Birkbeck College, at 5.30.—Prof. J. C. Schoute: Whorled Phyllotaxis.

Gresham College, at 6.—A. R. Hinks: Astronomy (3) (Gresham Lectures).

FRIDAY, May 12.

London School of Economics, at 5.—Dr. P. Giles: Modern Views of Indo-European Origins (1).

University College, at 5.15.—A. E. M. van der Meersch: Simplified Solutions for B.M. and S.F. Values for Rolling Loads (1);—at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (2).

Birkbeck College, at 6.—Dr. E. J. Russell: Recent Work with regard to the Influence of Soil Conditions on Agriculture (1).

Gresham College, at 6.—A. R. Hinks: Astronomy (4) (Gresham Lectures).

SATURDAY, MAY 13, 1922.

Contemporary Alchemy.

IN another part of this issue we print the concluding part of Sir Ernest Rutherford's account of his researches on the disintegration of the atoms of some elements by means of α-rays. The theory of atomic structure which postulates a small positive nucleus and sparsely distributed surrounding electrons indicates that a permanent change in the atom requires the disruption of the nucleus itself. This nucleus is also, according to modern views, an association of simpler parts, probably only units of positive and of negative electricity, which are the same in all atoms. If this arrangement can be altered, we should change one atom into another, or others. The forces binding the components of the nuclei of stable atoms must be very great, and in overcoming them a large expenditure of energy will be required. The swift α-particle expelled from radium is by far the most concentrated source of energy known, and by firing these α-particles through matter, collisions with the atomic nuclei might be expected to break up the latter.

This is the idea on which the work is based, and it has now, as Sir Ernest explains, received remarkable experimental confirmation. He found that, with nitrogen gas, hydrogen atoms were liberated, but these did not appear with oxygen or carbon dioxide. Such particles are, of course, produced in hydrogen gas, or substances containing hydrogen, but simple precautions ensure that the hydrogen particles otherwise observed do not come from hydrogen existing as an impurity in the materials. The H-particles from hydrogen have a range in air of 30 cm., and by interposing mica screens equivalent to this absorption, no such particles are observed as scintillations on a zinc sulphide screen. With nitrogen interposed between the source of α-rays and the mica screen, however, numerous scintillations appear.

By placing a thin film of metal over the source of α-rays, and having oxygen between this and the screen, the production of H-particles from metals could be investigated. Solid compounds were dusted over gold foil, which itself gives no H-particles.

With the exception of helium, neon, and argon, all the elements up to atomic weight 40 were examined. In no cases except boron, nitrogen, fluorine, sodium, aluminium, and phosphorus were any H-particles observed. No element of atomic weight greater than phosphorus (31) gave any effect, but only particles of range not less than 32 cm. were sought.

A very striking result was observed in the case of aluminium, since nearly as many H-particles were shot off in the backward as in the forward direction of the

colliding α-particles. This is explained by assuming that the H-particle in the aluminium atom is describing an orbit around the nucleus, when the direction of escape would depend on the relative positions of the α-particle and nucleus at the moment of collision with the satellite.

In the case of aluminium the maximum energy of the H-particle is 1·4 times that of the incident α-particle, and part of the energy must, therefore, have been derived from the nucleus itself. The disintegration is effected on an extremely minute scale; only about two α-particles in every million get near enough to the inner nucleus to dislodge an H-particle. If all the α-particles from 1 gram of radium were fired into aluminium, only one-thousandth of a cubic millimetre of hydrogen could be liberated in one year.

It has been surmised that the α-particle, or helium nucleus, of mass 4, is one of the units of which atoms are built up. The experiments referred to show that the hydrogen nucleus is also one of the units of structure, at least of some of the lighter elements. H-particles are only liberated from elements of atomic masses $4n+2$ or $4n+3$, where n is a whole number. Elements like oxygen and carbon, the atomic masses of which are $4n$, give no H-particles. This result would follow if the nuclei of the former elements are built up of helium nuclei, of mass 4, and hydrogen nuclei as satellites. The mass of the latter should not differ much from the free H-nucleus of mass 1·0077 in terms o=16, on account of the weaker binding of the satellite to the nucleus. If the nitrogen nucleus is made up of three helium nuclei of mass 12 and two hydrogen nuclei, the mass of the nitrogen atom should not be 14·00 but more nearly 14·01, as found by chemical methods. In the case of light elements the effective masses of the hydrogen nuclei should vary from 1·007 to 1·000 in different atoms, depending on the closeness of combination.

In earlier experiments particles of mass 3 with two positive charges appeared to have been liberated from oxygen and nitrogen. These, however, are now known to have their origin, at least in the case of oxygen, in the radioactive source and not in the volume of the gas.

We think it no exaggeration to say that these experiments are some of the most fundamental which have ever been made. It is not often that a scientific discovery excites interest outside the narrow circle of the laboratory or the scientific lecture-room. The discovery of radium by the Curies appealed to the larger world with a force which was equalled only by the profound interest aroused by the discovery of phosphorus by Brand in 1669, and of potassium by Davy in 1807, and so fundamental are the consequences of this new discovery that the intellectual world at large must follow with the keenest interest the progress of the experiments associated with the name of Rutherford. It was soon evident that increasing knowledge of the properties of radioactive substances was bound to alter fundamentally some of the cherished conceptions of the ancient science of chemistry. Sir William Ramsay held very tenaciously to the view that the immensely concentrated energy of the α-particle offered a means of testing that apparent simplicity of the chemical elements which they had succeeded in preserving, in trying circumstances, since the time of the alchemists. His experiments, however, could not at the time be convincing.

When Sir Ernest Rutherford went to Cambridge he had already made some progress in the most difficult task he has yet attempted. The means he used appear simple, as he describes them, but the experimental skill which was required to achieve these results is of a very high order. We feel sure that all our readers will join us in congratulating him on the work he is doing, and in expressing the hope that his further researches will continue to add to the splendid harvest of positive knowledge which is so rapidly growing under his hand.

It is obvious that the results so far achieved in this region are but the beginnings. There are many things we need to know, and some of the yet unsolved problems which suggest themselves may soon be cleared up by further researches. The chemist will be curious to know what is left when hydrogen is expelled from nitrogen, boron, aluminium, or other atoms. If boron is a mixture of two isotopes, of masses 10 and 11, these will be of the forms $4n+2$ and $4n+3$, both of which should give H-particles, as is found to be the case; but if lithium is a mixture of isotopes of 6 and 7, these ought also to give H-particles, although they were not detected under the conditions of experiment. If chlorine is a mixture of two isotopes, 35 and 37, the first is of the form $4n+3$, which should give H-particles, and the second of the form $4n+1$, which is not referred to by Sir Ernest Rutherford. Apparently, no H-particles were expelled from chlorine. This element, however, has an atomic mass higher than the limiting value 31, beyond which no H-particles were in any case found.

It may be that there is some change in the mode of building up the nucleus at this point, or, what seems more likely, that H-particles are, in fact, expelled, but are of such a range and velocity that they could not be detected in the present experiments. These difficulties will no doubt soon be cleared up, and we must await with such patience as we can the continuation of Sir Ernest Rutherford's work.

A History of Chemistry.

Die geschichtliche Entwicklung der Chemie. Von Dr. Eduard Färber. Pp. xii+312+4 plates. (Berlin: Julius Springer, 1921.) U.K., 312 marks; Germany, 78 marks.

DR. EDUARD FÄRBER'S "Historical Development of Chemistry" is one of those books that owe their existence to other books. It has been put together mainly with the aid of older works, more or less authoritative, on the subject of which it treats. As one turns over its pages, it is not difficult to trace the source of most of its statements. With the possible exception of the concluding section, which is concerned with the history of the present epoch, there is little evidence of original inquiry to be seen anywhere. Kopp and Lippmann have been drawn upon freely for the story of the rise and development of the chemical arts until the inception of phlogistonism, and Hoefer and Ostwald's "Klassiker," and Ostwald's "Lehrbuch der allgemeinen Chemie" have together furnished most of the material for the story up to the Revolution accomplished by Lavoisier and his co-workers. Much relating to the subsequent period has been gleaned from Kahlbaum's "Monographien," and from Hjelte's and Graebe's admirable histories of organic chemistry. For so much of the history of the progress of chemistry during what we may term our own epoch which has not yet been included in any systematic historical work, Dr. Färber has necessarily been driven for his information to special treatises, periodicals, and the published transactions and journals of the recognised chemical societies. To this extent he has certainly striven to exercise an independent judgment.

The works the author has consulted are excellent in their several ways, but it is well known to historiographers that much additional information has come to light on subjects which seemed adequately treated when certain of these works appeared. This is especially true of the earliest periods of chemical development. The researches of Egyptologists, for example, and the recent publication of works relating to Hindu and Chinese chemistry have made known many important facts concerning primitive operative processes essentially chemical in their nature. Manuscripts relating to later times have been discovered of which the existence was unsuspected. The real nature of others already known had not been revealed or was imperfectly understood. A more critical examination of ancient treatises has afforded new interpretations of what was obscure. Kopp's "Geschichte," published in 1843, when its author was barely of age, admirable as it is in many respects, has no longer the authority it enjoyed half a century ago. The "Beiträge," which appeared between 1869 and 1875, and the two volumes on "Die Alchemie in älterer und neuerer Zeit," based upon a fuller study of certain periods, no doubt supplemented and amplified the history. The "Entwicklung der Chemie in der neueren Zeit," printed and published in 1873 under the auspices of the Historical Commission of the Bavarian Academy, is but a fragment. It was written at a time of rapid change when Kopp was nearing the allotted span, and when his association with organic chemistry, never very intimate, was but slight. His editorial connection with Liebig's *Annalen* was probably the main source of his inspiration; certainly the Heidelberg atmosphere at that period had no quickening influence. Presumably Dr. Färber has been in a position to make use of this supplementary work. In any case, what is of permanent value in it has been incorporated in such later histories as that of Ernst von Meyer and of Ladenburg, but our author makes no mention of this additional matter.

It must be admitted that much of the information needed in the preparation of a history of chemistry that will comply with modern standards of historical research is not readily accessible. Some of it is scattered through publications comparatively unknown to the average professional chemist, as they seldom find their way into the ordinary chemical library. But some of this information has appeared in book form and is easily available, as, for example, Berthelot's "Les Origines d'Alchemie" and Roscoe and Harden's "New View of the Origin of Dalton's Atomic Theory," both of which works would seem to have escaped the author's notice.

Although the work is obviously a compilation—and it is but just to the author to state that he freely acknowledges his obligations by his abundant references to the sources of his statements—we by no means would imply that it is without merit. On the contrary, the general reader who is desirous of learning something of the rise and development of chemical science will find it of great interest, and most professed chemical students would widen their horizon considerably by an attentive perusal of its contents. It is written absolutely without bias and with an evident desire to present a well-proportioned and reasonably adequate account of the rise and progress of the science over the periods which the authors to whom the writer is mainly indebted have already traversed.

Considering that the book is intended for general reading, we venture to suggest that it would have added to its attractiveness if it were more freely illustrated. The interest of history is largely personal. The ordinary reader desires to know what manner of men they were who have collected the facts

of chemistry, and formulated its theories. He wishes to learn something of their characteristics, where and how they laboured, and what were the conditions and circumstances under which their discoveries were made. This no doubt would have involved search, wide reading, insight, and power of characterisation, but it would have added greatly to the human interest of the work, and have imparted vitality and colour to what we are constrained to say is a rather bald and impassive story of human achievement.

The author attempts in some degree to meet what we suggest by reproducing a copy of a print belonging to the National Germanic Museum at Nuremberg representing an "Alchemist's Laboratory"; by a picture of Berzelius as a rather slim young man in knee-breeches, well-developed calves, court shoes and a tight, cut-away coat, seated in a well-upholstered chair, watching, whilst reading, a highly idealised piece of distillation-apparatus, heated by a Roman lamp—a picture reproduced from No. VII. of Kahlbaum's "Monographien." When one recalls the humble kitchen in the Swedish Academy's apartments which, under the despotic sway of old Anna the cook, served the great chemist as his laboratory, this representation of the well-groomed philosopher in the perfectly-appointed parlour provokes a smile. It is pleasing, but it is not history. More realistic is Prautschold's better-known drawing of the interior of the Giessen Laboratory as it appeared in 1842. It represents a crowded assemblage of workers who resemble the German students of opera-bouffe, but it is probably characteristic. As the names of those figured are known it would have added to the interest of the picture to have given them. Some of them at least are not unknown to fame. The remaining plate is a photographic reproduction of van't Hoff's private laboratory at Amsterdam, taken from Prof. Cohen's memoir. The illustrations are probably given as types of laboratories of their respective periods, but happier selections are available and might have been introduced.

The ideal history of chemistry has yet to be written. There already exist a number of works of the character of the one now noticed, but many of them are not much above the range of ordinary school histories. The subject is worthy of a fuller treatment; its several periods should be dealt with in special monographs and in the manner of professed historians. The story during the last 70 or 80 years—infinitely the most fascinating and the most fruitful period in its history—has not yet been adequately handled. But the man who could handle it most effectively is probably too busy in augmenting it.

T. E. THORPE.

Antarctic Polychæta.

Australasian Antarctic Expedition, 1911–14, under the Leadership of Sir Douglas Mawson. Scientific Reports: Series C—Zoology and Botany. Vol. 6, Part 3, Polychæta. By Dr. W. B. Benham. Pp. 128 + plates 6 + Map 1. (Sydney: Government Printing Office, 1921.) *12s.*

THE labours of Kinberg, Grube, Ehlers, Gravier, Pixell, Ramsay, Benham (1909), and others, besides those described in the *Challenger* volume, have rendered us more or less familiar with some of the Antarctic Polychæts. The present memoir of Prof. Benham, an able and experienced observer, adds notably to our knowledge of such forms as have been obtained within the half-circle round the Antarctic land. The materials on which his report is based came chiefly from Commonwealth Bay, Adelie Land (Australian Antarctic), though a few were procured off Macquarie and Maria Islands and Tasmania, the collection containing fifty-eight species, of which eleven are new. In his summary of Antarctic forms hitherto obtained the author shows that the largest number of species belong to the Terebellidæ, followed in diminishing numbers by the Syllidæ, Phyllodocidæ, Aphroditidæ, Maldanidæ, Serpulidæ, and Sabellidæ, the other families having fewer numbers. Moreover, some species occur in large numbers, such as *Thelepus antarcticus*, *Harmothœ spinosa*, and *Potamilla antarctica*, a feature not uncommon in similar species in European waters. Of his new species, perhaps the most interesting is *Amythas membranifera*, from Commonwealth Bay, an Ampharetid which has an introversible frilled membrane instead of the usual oral tentacles.

The author has extended the distribution of various known species, as well as, by the aid of well-preserved examples, added to our knowledge of their structure, sexual variations, and otherwise. Careful investigation had led Prof. Benham occasionally to differ from his predecessors, but he shows fully and fairly the grounds on which his arguments rest; *e.g.* in the distinctions between Harmothoë and Hermadion. He does not enter into the structure of the foot in diagrammatic vertical section as Mr. Southern has done in the Indian forms from the Chilka Lake, probably because such is unnecessary in the discrimination of species, though it may be useful in critical cases. The careful methods adopted by Prof. Benham enabled him, for instance, to observe the chitinous supporting rod in the long metastomial cirri of *Pelagobia vigueri* which M. Gravier had overlooked. It may be open to doubt, however, whether his new species *Sphærodorum spissum* is not more closely connected with the European forms than is at present supposed.

This research still further emphasises the fact that no special polychæt fauna characterises the Antarctic seas, and that in all probability in the diatom-ooze of the great depths between Australia and the Antarctic shores even a proportionally greater number of novel types exist than have hitherto been procured. Again, some cosmopolitan forms make their appearance in the Antarctic waters, such as *Phyllodoce madeirensis*, *Glycera capitata*, *Cirratulus cirratus*, and *Serpula vermicularis*. It is curious, however, that *Hauchiella tribullata*, a Zetlandic Terebellid, is not included in the captures, though it was found at Kaiser Wilhelm Land in the American Antarctic region. The author did not meet with examples of the incubatory habit which was thought by Gravier to be a feature of these cold southern regions, *e.g.* in *Eteone gaini* and *Flabelligera mundata* amongst the polychæts, and in holothurians, actinians, and colonies of tunicates. It is well to remember, however, that the incubatory habit is seen in British seas from fishes to cœlenterates.

If criticism may be offered, it is that the author might have made the discrimination of his new and rare species more easily accomplished if he had given at the commencement of each a brief epitome of the specific characters. The accompanying ten plates have their figures fairly represented in lithographic ink, though they lack the fine touch of stone-engraving. The descriptive letters have been omitted from the figures throughout. The entire memoir is a credit to the Australian Government, and to Prof. Benham, whose ability and wide experience enabled him to treat the subject in an effective manner.

W. C. M'INTOSH.

European Archæology.

A Text-Book of European Archæology. By Prof. R. A. S. Macalister. Vol. 1, *The Palæolithic Period.* Pp. xv+610. (Cambridge: At the University Press, 1921.) 50*s.* net.

SEVENTY years ago the Scandinavian founders of European archæology regarded the shell-heaps or "kitchen-middens" as containing the earliest traces of man's handiwork. Ever since then it has been found necessary to shift man's beginnings further and further into the past, so that now Prof. Macalister is obliged to devote a whole volume, containing nearly 300,000 words, to reach the point at which his Scandinavian predecessors began their narratives. For the type of implement, in stone and in bone, found in the oldest shell-heaps the author adopts the recognised French term "Campignian," although he is of opinion that the culture represented in the shell-heaps was actually evolved in the Baltic Area. By a strange coincidence, if we are to follow our author implicitly, it is with the introduction of this shell-heap or Campignian culture into Ireland that the history of man commences in our sister-island. "No remains of the Palæolithic period to the end of the Magdalenian stage," writes Prof. Macalister, "have been found in the north of England or else in Scotland or in Ireland, some injudicious publications notwithstanding." The Professor of Celtic Archæology in University College, Dublin, has thus the advantage of surveying the ancient cultures of Europe from a land untrammelled by palæolithic tradition. His first volume covers cultural periods which are unrepresented in Ireland.

Where, when, and how, then, does the modern story of European archæology begin? One may reasonably complain of having to wade through some two hundred preliminary pages before reaching the point at which Prof. Macalister commences his archæological narrative. The first chapter is spent in defining what archæology is and what it is not; the second is devoted to the elements of geology, the third to the evolution and classification of mammals, the fourth to the evolution of man and classification of races, the fifth to eoliths and to *eolithists*, the name which the author gives to those who believe in eoliths as products of human hands. As the following passage shows, Prof. Macalister refuses to begin his archæological narrative with eoliths:—

"The question that these flints present to us is primarily: Are they the work of a conscious agent, fashioning them for a definite purpose, or are they not? The answer to this question appears to be almost wholly subjective, not objective, and is therefore outside the region of scientific study, except perhaps for the psychologist."

We fear that Prof. Macalister understands as little of psychology as of eoliths. For him, true archæology begins with types of flint implement which even a child can perceive have been artificially fashioned.

Archæology is construed in a wide sense by Prof. Macalister. It is made to include not only all things which have been made or used by past generations of mankind, but also skulls, bones, teeth, psychology, and religion. For a writer who warns his readers on almost every page against possible fallacies, it is somewhat daring for him to assert that "Man develops a religious instinct." Then, again, when discussing the "psychology of middle palæolithic man"—men of the Neanderthal type—he not only boldly asserts that they had a religion, but proceeds to draw a picture of this long dead and extinct type of humanity sitting round the fire and discussing momentous problems.

"One would tell of a dream that he had had, in which the dead had appeared to him; another would relate how something, he knew not what, but which surely was not of the common things of nature, had

startled him when he was wandering abroad in the gloom of the forest" (p. 343).

Such fancies may find a place in a schoolboy's essay, but are altogether out of place in a massive work devoted to the archæology of Europe.

The illustrations, which are excellent and numerous, make up for much that is deficient in the text. Students will also be thankful for references to many recent papers and monographs. There is no doubt a real need for such a text-book as this written in English and designed for the use of students of archæology—a text-book to serve as a standard work. We only regret that the author, while displaying a most commendable and painstaking industry, has not risen to the height of his opportunity. A. K.

Indian Game-Birds.

The Game-Birds of India. By F. C. Stuart Baker. Vol. 1, *Ducks and their Allies* (*Swans, Geese, and Ducks*). Second edition. Pp. xvi + 340 + pl. xxx (4*l.* 4*s.* net.) Vol. 2, *Snipe, Bustards, and Sand-Grouse.* Pp. xvi + 328 + pl. xix (3*l.* 13*s.* 6*d.* net.) (Bombay: Bombay Natural History Society; London: J. Bale, Sons, and Danielsson, Ltd., 1921.)

THE first of these volumes, dealing with Ducks and their allies, is the second edition of a work published by the author in 1908, which again was a reprint from a series of articles which appeared in the Journal of the Bombay Natural History Society. The matter has therefore had the advantage of two revisions and is brought completely up to date as regards nomenclature and records. The second volume, now before us, deals with birds which are included by the sportsman among the game-birds, though in scientific classification they are not so. These are the Snipe, Bustards, and Sand-Grouse. Two further volumes are promised on the Pheasants and Partridges, and with these four by his side the Indian sportsman and amateur naturalist will be very completely equipped not only to identify the game-birds he commonly meets with, but to obtain all the information in regard to their habits and occurrence that is known. Mr. Baker, though now for some years retired from service in India, spent the greater part of his life there, and in these volumes he has given us much of his own observations and experiences; to these he has added contributions from others, both previously published and derived from information sent him by his many Indian correspondents. As a result we have here a most complete account of the life history of these favourite birds.

In every case a good description of adults and nestlings is followed by paragraphs on the distribution, nidification, and general habits, while every species is illustrated with coloured plates. These are most of them by Mr. H. Grönvold, though some of those in the first volume are from the brush of Mr. G. E. Lodge and the late Mr. J. G. Keulemans. They are reproduced by chromolithography in the case of the Ducks, and by the three-colour process in the second volume. The chromolithography is certainly softer, and perhaps gives a more artistic result. In the three-colour process the colours are decidedly sharper, and better defined, though the very shiny paper necessary for this process certainly detracts from their artistic appearance.

Perhaps one of the most interesting facts recorded in these volumes relates to the habits of two species of sand-grouse, *Pteroclurus alchatus* and *P. senegalensis* (formerly known as *P. exustus*). Although these birds inhabit the dryer and more desert regions of north-west India and Central Asia, they are, unlike some other desert forms, unable to do without water, and resort in enormous flocks to well-known watering-places at certain fixed hours to quench their thirst. It has always been stated by native shikarees that when they have young broods they convey water to them by thoroughly soaking the feathers and the breast and underparts, and that the young birds suck the water thus conveyed to them. This story has been confirmed by Mr. Meade Waldo, who has repeatedly bred *P. alchatus* and other species in confinement and has watched the process of the male saturating the feathers of his breast and subsequently satisfying the thirsty brood.

Nearly all intelligent travellers and even residents in tropical countries have experienced the irritation and annoyance of being unable to identify the strange forms of animal and vegetable life with which they come in contact. Such works as the present, with its beautiful series of coloured plates and carefully prepared descriptions, cannot fail to be of the greatest assistance to all those whom duty or pleasure take to India, and we must congratulate Mr. Baker and the Bombay Natural History Society on their enterprise in supplying two such fine volumes at a comparatively reasonable price as things are at present. We shall look forward to the appearance of the other two volumes promised within a reasonable period.

Water Flow in Pipes.

Hydraulics of Pipe Lines. By Prof. W. F. Durand. (The Glasgow Text Books of Civil Engineering.) Pp. xvi + 271. (London: Constable and Co., Ltd., 1921.) 18*s.*

THE subject of the flow of water in pipes and channels is not only of very considerable historical and scientific interest, but is also one of

great practical and economic importance. It is frequently stated that hydraulics is an empirical science because water differs from the ideal fluid to such an extent that the theoretical hydrodynamical investigations are not of much value to the hydraulic engineer. While this in a measure is true and it is necessary to resort to experiments to determine the exact form of the formulæ which express the flow of water along pipes and the co-efficients to be used in them, nevertheless, there are many problems connected with the flow of water in mains which are capable of analytical treatment, and the volume under notice has for its principal aim the discussion of these problems.

In chapter 1 the general hydraulic principles of flow are discussed and empirical formulæ such as those of Chezy and Kutter are quoted, tables of co-efficients to be used with them for clean pipes being given. There is no attempt whatever to give particulars of modern researches, and so far as this chapter is concerned with loss of head by friction, no experimental work done during the last thirty-five years is considered worth mentioning. As regards losses by bends and elbows recent researches have been referred to, but no consideration is given to the very important question of the change in the carrying capacity of a pipe with time. The general principles are, however, clearly discussed, and it may fairly be said that this chapter is written as an introduction to the chapters which follow, in which the problems of the surge chamber and water hammer in pipe lines are very fully discussed.

The two succeeding chapters deal very fully with stresses in pipe lines, with the materials of construction, and with the design of pipes. The last chapter of the volume deals with the flow of oil along pipe lines. The important effect of temperature on the viscosity is emphasised and a curve is given showing how the pressure drop per mile can be obtained when the temperature is changing.

There are four appendices in which certain special theoretical problems are dealt with. In Appendix 1 the general theory of pipe line flow is considered from the theory of dimensions. In this connection it is surprising to an English reader to find no reference to Lord Raleigh, or to the work of Stanton and Pannell, or Lees, and throughout the whole book there is very little reference to much important work that has been done in this country. To English readers also such symbols as (*pf2*) and (*f3s*), meaning pounds per square foot and cubic feet per second respectively, may appear a little awkward, but the notation used throughout the book is summarised at the commencement. The work should prove of value to serious students of the subject.

F. C. L.

Recollections of a Geologist.

Memories of a Long Life. By the Rev. Canon T. G. Bonney. Pp. iv+112+vii. (Cambridge: Metcalfe and Co., Ltd., 1921.)

A LIMITED edition of this little book has been printed. It is meant primarily for Cambridge readers, but will be perused with affectionate interest by the many other friends of its author. It has also some wider appeal as the unaffected and revealing life-story of a last-century Don. Not many of us can aspire to a retrospect so gratifying in its entirety; and we congratulate the author on his enviable possession.

Beginning in 1837 with the hearing of minute guns on the death of William IV., the "Memories" cover a period of over eighty years (and are happily still continuing). Of the wide scientific achievements of their narrator they tell little, but are vivid with incidents and anecdotes of his boyhood, undergraduate days, and later professional life in Cambridge and London, with recollections of eminent men and abnormal weather. In the parlance of relativity, the events for the most part pertain to a particular system of reference and would scarcely be recognisable as events in another system; but they combine, within their limits, into a concordant and sharply individualised picture of a career "crowded with culture." They exhibit a life of continuous mental and bodily activity; terms of strenuous duty alternating with pleasant vacation tours in the Alps and elsewhere, usually fruitful in scientific results; and in their long range they recall the changes, both in material things and in mental outlook, that have become apparent during their course. It is a cheerful picture, in which we may occasionally catch the trace of vigorous old controversies that, like the little whirlwinds of hot weather, have now and again raised temporary commotion within the sphere of their impact without disturbing the broad serenity of the plain.

There is strong spice in the caustic remarks on the unseemly behaviour and dress of some of the undergraduates of to-day, and in the comments on the motor-car and bicycle, the latter of which "shoots out silently from hidden byeways, the rider never dreaming of using his bell." But the good-nature underlying it all is illuminated by the episode of a happening, years and years ago, when the author, then junior Dean, cleverly detected an undergraduate in a prankish breach of order in Chapel, and brought him before the Seniority with a stern demand on its unwilling members that "if you do not send him down you must appoint some one else to sit there in future,

for I will not"—this Draconian severity being pressed for because "the penalty was not really so heavy as it seemed, for as I privately knew the man had just kept his term"!

The index should be read; it is an epitome of the book.

Our Bookshelf.

Der Torf. Von Prof. Dr. H. Puchner. (Enke's Bibliothek für Chemie und Technik unter Berücksichtigung der Volkswirtschaft: Band I.) Pp. xvi+355. (Stuttgart: Ferdinand Enke, 1920.) 40 marks.

PEAT is always an attractive subject for the investigator, and particularly for the inventor, as it seems to promise so much in return for so little effort. It lies on the surface and needs no expensive mining operations; it is often on the top of a hill and can be run down to the consumer by gravitation, and it is capable of yielding fuel, ammonia, and various oils by distillation or heating processes, for which it can itself provide the necessary energy.

The book under notice gives a useful summary of the properties of peat, especially of those studied by the German workers, and it will prove useful to prospective investigators who wish to know something of the nature of the material they have to handle. The great difficulty up to the present has been the drying: in its natural state peat may contain 90 per cent. or more of water, and this has to be reduced considerably before economic utilisation is possible. So far no method that is generally satisfactory seems to have been evolved. The author helps by giving an account of the methods adopted in Carinthia, Oldenburg, and elsewhere, as well as a list of methods proposed or used in factories where peat is converted into saleable products. The number of methods of utilisation suggested or actually tried is considerable. During the war attempts were made in Germany and Sweden to use it for firing railway engines, but it was found necessary to fill not only the tenders but also one or two waggons with fuel if any length of journey was contemplated. Much more successful are the efforts to convert peat into power gas, and one feels on looking through the book that the problem of utilisation of peat must surely be near its solution. It would certainly add to the resources of the world if satisfactory methods could be worked out.

The Homogeneous Electro-Thermic Effect. (*Including the Thomson Effect as a Special Case.*) By Carl Benedicks. (Ingeniörs Vetenskaps Akademiens: Handlingar Nr. 5, 1921.) Pp. 117. (Stockholm: A.-B. Svenska Teknologföreningens Förlag; London: Chapman and Hall, Ltd., 1921.) 15*s.* net.

THE Swedish Academy is issuing in English a series of memoirs on scientific subjects in order to make the work of Swedish men of science more widely known, and the volume under notice is the fifth to be issued. It deals with the transport of heat along a conductor through which an electric current is passing, and the author concludes from his measurements that there is, in addition to the Kelvin effect, a further flow of heat with or against the electric current even when the conductor is homogeneous and originally at a uniform temperature. His measurements are in general made on long cylinders, the centre of each being turned down to a narrow neck. The electric current through the neck causes a transport of heat to one or other side of the neck, and the difference of temperature of the two sides is measured by thermo-junctions. This difference does not vary with the magnitude of the electric current according to the same law as the Kelvin effect, nor is it always of the same sign as the latter. The author proposes to call this new effect "the homogeneous electro-thermic effect."

The Wisdom of the Beasts. By C. A. Strong. Pp. x+76. (London: Constable and Co., Ltd., 1921.) 5*s.* net.

THIS is not a zoological treatise on animal instincts and the like, but a series of philosophical fables of excellent humour—indeed the prefatory quotation from the Prologue to Phædrus' Book I. makes us shrewdly suspect the author of exquisite satire directed at relativity and other scientific concepts. The fable of "The Bird and the Fish" will cause amusement to the disciples of Einstein:—a young bird, inexperienced in the phenomenon of moving air and in its effects, is set thinking by the fact that on a certain day it took less time than usual to fly from the church steeple to the stream, and more than usual to make the return flight: after much cogitation it satisfies its philosophic soul thus:—"Ah! I have it at last; what has changed is not the field, but the clock. By flying away from a clock you alter its time-keeping so that it loses, and by flying towards it you alter its time-keeping so that it gains. The time-keeping of clocks is not a fixed and unalterable thing, but depends on whether you move or stand still." And such is the style of the majority of these fables.

Analyses and Energy Values of Foods. By Dr. R. H. A. Plimmer. Pp. 255. (London: H.M.S.O., 1921.) 6*s.* net.

THIS work, which was carried out for the War Office authorities, contains the most comprehensive series of food analyses performed in the British Isles. As the author points out, they are best regarded not as a replica of but as a supplement to the very complete set of data by Atwater and Bryant, U.S. Department of Agriculture. In some cases the number of analyses is not great, but since the results are from foods as actually supplied in Great Britain, they carry more weight in this country than more numerous figures published for other countries. The tables are very carefully arranged, so that the composition of the entire food, or any part of it, may be seen at a glance. There is also an excellent summary of analyses in a form suitable for calculation. Information is given regarding the methods employed, and a short appendix tabulates the common food stuffs which do, and also those which do not contain accessory food factors or vitamins. The volume undoubtedly represents a valuable and distinct advance in knowledge.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Science at the Post Office.

I HAVE always regarded expressions of opinion in the leading articles of NATURE as founded on ascertained facts impartially considered, and it is therefore with much regret that I feel impelled to protest against the article entitled "Science at the Post Office," which appears on the front page of your issue of April 1.

I shall try to put the writer's main contentions, and my replies to them, very briefly.

(1) *Complaints regarding the telephone service after the war are closely connected with the question of the technical qualifications of the engineering staff.*

This is not true in the sense intended to be conveyed. It is the easiest matter in the world to demonstrate that the complaints do not arise from any conditions involving science or research, but are due to the quite simple and commonplace fact that the home service had suffered for five years by the withdrawal of over 13,000 of its engineering staff for military duties, and by the loss of a large proportion of its experienced telephone operators.

The telephone system transferred to the State in 1912 was in urgent need of reconstruction and extension on a great scale. Such work on what may be called a living organism, and one very complex and sensitive, has to be carefully planned and executed. It was in full swing in 1914, when it had to be abandoned at the call of vital national necessity. Its resumption after the war was attended for some time by great and well-known difficulties in the supply of materials and in the retransformation of factories to peace conditions. It is now well in hand again. New operators have been trained, and what is needed to put things right is the construction of exchange buildings, switch-boards, and cable plant in adequate volume. The same conditions have applied to all nations involved in the war, and have no direct relation to the efficiency or scientific attainments of their engineering staffs. Nowhere was the post-war deterioration of telephone service more conspicuous than in the United States of America, although the depletion of telephone resources in that country lasted for less than half the time, and was proportionately very much less serious than in Great Britain.

(2) *A scheme, introduced in* 1907, *for recruiting* 25 *per cent. of P.O. engineers by open competition has remained in abeyance since* 1912, *and has now been replaced by a scheme whereby only* 20 *per cent. of new entrants will be obtained by open competition.*

The implication here is that standards of qualification, set up by a former Engineer-in-Chief, are now being reduced, but the facts are quite otherwise. There were good reasons for suspending the scheme in 1912, as practically the whole engineering staff of the National Telephone Company was then transferred to the Post Office, and had to be equitably absorbed in its engineering organisation. Since the war very few new appointments to the engineering classes have been made. The scheme of 1907 provided for the admission of college-trained youths by an examination considerably lower than that of an engineering university for a science degree. The present scheme requires all candidates to possess a science degree before they are eligible to sit for the competition for Assistant Engineerships, and the character of the examination is fully equal to the degree examination of the universities.

Another important point ignored in your article is that the present scheme has set up a separate open competitive examination, for which young men who have studied at universities and technical colleges are eligible. The character of this examination is a little lower than that for graduate Assistant Engineers, and successful competitors will be appointed as "Inspectors" in the Engineering Department. In this position they will be eligible, along with other selected Post Office employees, for a further series of competitive examinations for a further 20 per cent. of the vacancies for Assistant Engineerships (in the same subjects as in the examination for graduates but of a slightly less advanced grade) as well as for promotion in ordinary course. It is therefore a wide departure from the truth to say or imply that the proportion of full-time college men among recruits for Post Office engineerships has been limited to 20 per cent. And, quite apart from these outside recruits, I maintain emphatically that no man who is not, in the best sense of the word, a college student has any chance of appointment as a Post Office engineer. The fact that a man has had the grit and capacity to win his spurs by evening studies, extending over a period of many years, while following his daily employment is, to my mind, the reverse of a disqualification. Among the thousands of young men in the lower grades of the Post Office Engineering Department there exists a splendid recruiting ground for the higher positions. These men are selected with care in the first instance, and they are watched and reported on with equal care. They know that promotion depends on character and efficiency. The idea of "the field-marshal's baton" is rife among them, and I, for one, sincerely hope that the Post Office will always give it full encouragement. I have no fear of being charged, in any informed quarter, with belittling the need for mathematical and scientific attainments of the highest order in connection with the telegraph and telephone services. But the field of the Post Office Engineering Department is so wide that its everyday work calls for qualifications of many different kinds, and I speak from knowledge and experience when I say that the engineer who combines high character and business and administrative capacity with long Post Office training and continuous self-education is an officer of first-class practical value for whom there will always be abundant room.

(3) *The Chiefs of the Post Office Engineering Department should be men from outside the department, who have reached a position of eminence in the general engineering profession.*

I need not say much on this point. Two of my four Post Office predecessors in the position of Engineer-in-Chief, during the past thirty years have been Presidents of the Institution of Electrical Engineers, and others have only been prevented by the shortness of their term of office from attaining the same position. No one who understands the complexity of modern telegraph and telephone engineering will contest the statement that the position of Engineer-in-Chief will be better filled by the most highly qualified telegraph and telephone engineer and administrator in the country than by the most highly qualified general engineer. The American Bell Telephone Organisation is rightly held up to us as a model. In no case would the heads of that organisation dream of appointing a chief engineer who had not spent the main part of his lifetime in

telephony. The senior ranks of the department—Assistant Engineer-in-Chief, Staff Engineers, and Superintending Engineers—contain many men much more fully qualified for the premier position by capacity, general and scientific education, and special engineering and administrative experience than any outside engineer could possibly be, and the Postmaster-General is to be congratulated upon the field of choice at his command. This is well known to the whole staff, and I need say nothing of the effect upon its *moral* and *esprit de corps* which would follow the adoption of the principle recommended in your article.

I am afraid I have already over-trespassed upon your valuable space, otherwise I could give much information as to the brilliant scientific work performed by Post Office engineers. Many of their productions are classics in the field of telegraph and telephone engineering and research.

The Post Office service is a "silent service," except when gratuitous and undeserved attack stings it into retort. I can without hesitation challenge any critic to produce experts in any branches of telegraph or telephone service who would not be at least equalled by Post Office officials whom I could name.

W. Noble,
Engineer-in-Chief.

General Post Office (West), London, E.C.1,
April 19.

Sir William Noble places a construction upon the words used in our article which they cannot reasonably bear. The purpose was to direct attention to the Report from the Select Committee on the Telephone Service (1922), a document very generally admitted to be one of the most important and valuable of parliamentary papers issued in recent years; and we believe the article to which Sir William Noble refers to be a fair comment on a matter of great public interest. The Committee definitely says in this Report: "We cannot agree with the trend of Post Office evidence that from a telephone point of view the existing organisation works perfectly well, however cleverly managed it may be," and therefore substantially finds that there was good foundation for the complaints concerning the inefficiency of the Post Office telephone service: the Committee, in consequence, recommends a "*thorough reform*" (our italics) in the Post Office organisation. The minutes of the evidence taken by the Committee are contained in a public document (H.C. 191 of Session 1921), and therefore the names of the witnesses and particulars concerning them can be readily ascertained by those who so desire. Now, it is true that evidence was given by witnesses representing newspaper organisations, namely, the Press Association and the Newspaper Society; on the other hand, apart from the Post Office officials, the great majority of the other witnesses who came before the Select Committee attended in order to represent important organisations of various kinds, some fourteen in all, such as Chambers of Commerce, Agricultural Associations, and two Municipal Corporations. The general trend of the evidence of the latter witnesses amounted to a criticism of the quality of the telephone service, and although a great volume of the fault-finding was directed against the administrative system of the Post Office, many of the adverse comments made by the witnesses referred to work of a technical kind.

The volume in which the evidence in question is to be found was indicated in our article, and all who so desire can therefore consult the actual statements of witnesses as put on record therein, and can at the same time naturally draw their own conclusions in relation to the matters under investigation. We take, and have long taken, a deep interest in the utilisation of science in the public departments, and many sources of information on this matter are open to us; in consequence, we have considerable personal knowledge of the conditions prevailing in the technical branches of the various government departments, including the Post Office.

To deal with the first of Sir William Noble's contentions. We do not deny that during the period of the war the Post Office services had had to be carried on under exceptional difficulties. We also had information some time ago from American sources showing that the telephone service in America had deteriorated during the war period after the U.S.A. Government established its control upon the telephone undertakings; afterwards we learnt from American business men that the telephone service in their country began at once to improve as soon as the government control was removed, and was quickly brought again to a high level of efficiency. We fail, to see, however, the connection with the war situation alluded to by Sir William Noble in his letter, and the fact to which attention was directed in our article, namely, that foreign telegraph and telephone administrations have for a long time past demanded a higher standard of technical qualifications from applicants for positions in their engineering departments than has the Post Office.

As regards the second of Sir William Noble's contentions, we cannot understand how he arrives at the conclusion that the language employed in the reference in our article to the Post Office recruiting scheme of 1907 contains an implication that "standards of qualification, set up by a former engineer-in-chief, are now being reduced." The purport of our remarks on the subject is to the effect that we disapprove of a policy the consequence of which will be to reduce the percentage of engineers entering the Post Office by open competition below that represented by Post Office officials to the Select Committee of 1912—an extract from the Report of which is given in the article—as being then necessary. Our contention is that, responsible Post Office officials having stated publicly ten years ago, for the reasons given in the extract quoted, that it was "undesirable to limit the field of recruitment for the class of assistant engineers to those within the Department," and also that it was "important that 50 per cent. of the vacancies should be filled by young men of wider education and higher engineering attainments than are usual amongst Post Office servants," it cannot be right, and in the interests of the public service, now to reduce the percentage of engineers to be recruited by open competition to 20 per cent. only, as would appear to be the policy of the Post Office at the present time.

Within the limits of space at our disposal we are unable to go into details in connection with the method proposed for recruiting the subordinate grades of the Post Office engineering department: we were, of course, fully aware of the scheme outlined by Sir William Noble in his evidence before the Select Committee (Q. 2227); an opportunity may occur for dealing with the subject at a later date. However, it may be said at once that we fully recognise, and are in entire agreement with the view, that an avenue of promotion to the highest rank in the Post Office should be open to every *properly and sufficiently qualified* individual, irrespective of when or where he reaches the standard of qualifications essential to enable him *skilfully* to discharge the higher duties, and irrespective also of the grade in which he first entered the public service. But on account of the facilities, such as County Scholarships and otherwise, which are now open to every young man of ability, regardless of the means of his parents, for obtaining

at an early age the highest standard of technical education available in this country, and for other reasons, we are of opinion—and our opinion is shared by important bodies representing the engineering profession—that the Post Office recruiting scheme outlined by Sir William Noble in his evidence is not of a kind which will best meet the needs of the situation, nor one which most effectively promotes the best interests of the State. Schemes of internal departmental examinations for promotion purposes are unsatisfactory; there is no guarantee that they will not be at some time reduced to a farce, *e.g.*, such as by allowing candidates to qualify in single subjects at relatively long intervals of time, and there are also other objections to such an arrangement.

As to Sir William Noble's third contention, we recognise, of course, that in the past the position of engineer-in-chief at the Post Office occasionally has been held by distinguished men, but we hold that quite a different stamp of early education and training is now required to produce the leaders who are to be called upon to devote their later years to administrative work in a technical sphere. Conditions have long passed the pioneer stage when knowledge had to be acquired and accumulated little by little, and day by day, in the course of daily work in order to build up materials for the science of one's particular branch of technology for the use of future generations of workers in that field. There are in the ranks of the Post Office engineers men of considerable technical ability, and nothing has been said to the contrary in these columns. But we are as averse to a government department relying for its reputation mainly on the eminence of one or more of its former chiefs, as we are to a young man claiming distinctions on the mere ground that one or more of his forebears was, or were, undoubtedly a man, or men, of brilliance. Further, one swallow does not make a summer, and, on the same principle, a small percentage only of able men in a large and complex department cannot possibly maintain it at a proper level of efficiency.

What we desire to see introduced is the method of selecting departmental chiefs indicated in our article, and the adoption of the procedure there recommended. We, therefore, cannot contemplate with the same satisfaction and equanimity, which Sir William Noble appears to do, the present situation. The status of the chief technical adviser in a government department dealing with the highly scientific and complicated problems associated with the telegraphs and telephones is at present considered to be equal in the matter of salary—the outward indication of status—to a position the importance of which is estimated to be one-half only of that of the chief administrative officer of the Department, and just about two-thirds of that of the administrative officer in the second position. We are consequently in agreement with the recommendations of the Select Committee which proposes the introduction in this country for the management and control of the technical services of the Post Office of an organisation similar to that of the Administrative Board of the Swedish Telegraph Department, and it is to be hoped that measures will be taken at the earliest possible date to carry out a thorough reform of the Post Office on the lines indicated in the Report of the Select Committee of 1922.

THE WRITER OF THE ARTICLE.

Discoveries in Tropical Medicine.

IN NATURE of April 29 there occurs, beginning at line 30 of page 549, the following statement: "The fact is that Manson's 'suggestion' that the Filaria of elephantiasis is actually carried by mosquitoes from the blood of one person to that of another remains to this day a 'suggestion.' It has not been established as a fact."

This statement is so strangely erroneous, both in concept and in fact, that were it not made in a letter professing to rescue truth from misrepresentation, written by one who in his own department of natural science has long enjoyed a commanding position, it would be kinder to all concerned to ignore it.

From the context it is evident that the term "filaria of elephantiasis" refers to the parasite known in pathology as *Filaria bancrofti*, this being the species responsible for a variety of pathological conditions in man, among which most pathologists, but not all, include elephantiasis.

Now in pathology the name *Filaria bancrofti* belongs to the adult worm, which lives not in the blood but in the *lymphatics*; we must assume therefore that by the expression "Filaria of elephantiasis . . . carried from the blood" is intended not the adult but the embryonic form of the worm—known to pathologists as *Microfilaria bancrofti*—which does occur in the *blood*.

Making these necessary assumptions, in the attempt to clarify an ambiguous statement, the interpretation is that a "suggestion" is extant that *Microfilaria bancrofti* is carried by mosquitoes from the blood of one person to that of another, and that this "suggestion" has not been proved.

Such a suggestion may have been made by some unimaginative individual; such an accidental mechanical transfer might conceivably occur; but since the microfilariæ cannot develop in the blood, their transfer from the blood of one person to the blood of another would throw no light on the question—how do the microfilariæ in the *blood* of one person become the filariæ in the *lymphatics* of another? The suggestion would remain—like Touchstone's shepherd's suggestion as to the cause of night—an idle and obtuse suggestion, not worth verification.

Any one acquainted with the facts and their implication, desirous of proclaiming the truth to readers of NATURE, who are not all parasitologists and pathologists, would not introduce an ambiguous term like "filaria of elephantiasis" into his text; for although *Filaria bancrofti*—which is the worm often associated with elephantiasis—is without doubt abundantly pathogenic to man in other ways, there are still some pathologists who are not convinced that it is responsible for the particular disease elephantiasis. The possibility should have been kept in mind of an inference being drawn that because some doubt still existed as to the full extent of its pathological significance the pathogenetic character of the filaria is still a matter of "suggestion"—a lamentably erroneous inference.

Readers of NATURE should have been informed that the whole history of *Filaria bancrofti* and its relations to man and to mosquitoes is to be found in text-books, some of them written by men who have themselves confirmed the facts and know at first hand what they are describing. To be brief: it has been known for many years that the microfilariæ floating in the bloodstream of an infected man are sucked up with his blood by mosquitoes of many kinds that bite him after sundown; that they get into the stomach of the mosquito, and thence into the insect's muscles, where they grow and develop; and finally, that as larvæ some of them get into the insect's proboscis, whence, when the insect bites other men, they escape on to the victim's skin and bore through into his lymphatics. Every stage has been followed, though naturally for the final stage the evidence is based—quite legitimately—on experiments in the laboratory with an analogous species of filaria.

The discoveries of those stages in this wonderful

history that are passed in the stomach, muscles, and body-cavity of the mosquito, and of the necessary intermediation of the insect in the spreading of filarial disease among men, were made by a busy medical practitioner, working alone in China, in 1877. They were reported at a meeting of the Linnean Society held in March 1878; they were published in the zoology section of the Society's Journal for 1879; and an amplified account, with a plate of 46 figures representing every stage of the worm's development in the mosquito, from embryo in the stomach to larva in the body-cavity, subsequently appeared in the Transactions of the Society for 1884, at p. 367.

Not even the loneliest man, of course, works alone; as Carlyle says, "all past inventive men work with him there." But in workers there are varieties of aptitude and varieties of circumstance; and in discoveries there are varieties of worth. The discoveries of the highest class are those that enlarge the boundaries of science, that increase understanding, and open out new fields of action. The discoveries, worked out in unpromising circumstances, by that great original genius Patrick Manson, and reported to the Linnean Society in March 1878 and 1884, were of this kind: they established a great luminous principle of pathogenesis — the principle of the necessary intermediation of the bloodsucking insect: and of every man who applies this principle anew it may be truly said that always in the background Patrick Manson, may peace be with him—acknowledged or forgotten—"works with him there."

Nectar-Sipping Birds.

THE device of *Mirafra Assamica* to reach the nectar in the flowers of Castanospermum (noted in NATURE of April 15, p. 489) has its parallel among British birds. The blooms of several Asiatic species of rhododendron contain much honey, and many of these are defaced at this season by the great tit (*Parus major*), the blue tit (*P. cæruleus*), and probably the coal tit (*P. ater*) pecking holes in the tube of the corolla and tearing away the upper petals to get at the nectary. In some gardens bumble-bees have learnt to make a similar short cut to the nectary of *Salvia patens*; the legitimate entrance, which is furnished with a neat mechanism to ensure cross fertilisation by humming-birds or long-tongued Lepidoptera, being too narrow to permit access for Bombus. Knowledge of the trick, however, is not universal among bumble-bees; for I have found that in some gardens the blossoms of this Salvia remain intact.

Aeroplane Crashes: The "Hole in the Air," the "Spin."

THE kind of accident in which Sir Ross Smith and Lieut. John Bennett lost their lives appears to be due to an attempt on the part of the pilot to change the direction in which the aeroplane is moving more abruptly than is consistent with its momentum. Suppose, for example, that the aeroplane could be instantly turned round to face the point from which it had come, its momentum would inevitably cause it to travel an appreciable distance tail first. An approach to this condition constitutes the "hole in the air" of the early airman, and is the harbinger of the "spin": it is the equivalent of "skidding" in the motor-car and is due to exactly the same cause, namely, momentum run riot.

As the motion of translation through the air (the one essential condition to the flight of heavier-than-air machines) is being lost the aeroplane begins to fall, and it is difficult to imagine that the pilot can do anything to arrest the fall except perhaps when it accidentally takes the form of a slanting nose-dive. Immunity from this class of accident can only be attained by judicious "banking" on curves of a radius suitable to the aeroplane and its velocity at the moment, and the complete avoidance of quick-turning movements undertaken for any purpose. Is it possible that in some aeroplanes the steering appliance is unnecessarily powerful and apt in that respect to deceive the pilot?

W. GALLOWAY.

The Athenæum, April 18.

DR. GALLOWAY directs attention to an important aspect of aviation in his reference to a recent accident. The type of failure—a spinning nose-dive—is unfortunately too common, and on any reasonable statistical basis may be expected to remain so until improved aeroplane design is achieved. Whilst rapid turning facilitates "spinning" the fundamental cause is peculiar to the aeroplane and a property of wing form and arrangement. The support for an aeroplane arises from the aerodynamic characteristics of the wings, and a fundamental change occurs when the angle of attack exceeds some 15 or 20 degrees. Above this critical angle the ordinary motion of an aeroplane is extremely unstable and the natural motion is a spin with the nose well down; the details of the instability are clear, but the remedy is unknown and only dimly foreseeable. The difficulty put before the pilot by the instability is accentuated by simultaneous loss or reversal of control. Scientific research is here required; it is, indeed, very urgently needed, but the prospects of obtaining the opportunity are far from good. Financial stringency and insufficient sympathy for research by the Air Ministry are the great difficulties, and not lack of scientific ability in the country. It is to be regretted that the loss of famous men is required to give point to a problem of long standing and that the Aeronautical Research Committee has not the necessary authority to carry out work which its reports show that it recognises as very important.

L. BAIRSTOW.

The Blood-cells of the Oyster.

THE blood-cells (leucocytes) of the oyster have been a subject of great interest ever since Lankester first observed them crawling on the outside of the body parts of the oyster. Recently I have found that these leucocytes will live for 3 or 4 days in sea-water in dishes. If the leucocytes be set free by teasing up the heart of an oyster or by placing pieces of the palps or bases of the gills in sea-water in a petri dish, they are seen at first to be aggregated mainly in masses, but within ten minutes to half-an-hour it will be found that the leucocytes are spread over a large portion of the dish and creeping away from the masses in a flattened amœboid condition on the bottom of the dish or even on the surface film. At the end of 3 or 4 days the cells round off and die. The length of time they remain alive, however, should make these leucocytes—which are very easily obtainable—valuable as subjects for physiological investigations, and further, suggests that it might be possible to *cultivate* them in an appropriate medium under appropriate conditions.

The mode of propagation of leucocytes in oysters is not known, and certainly no definite organ is known to produce them. A division of a living leucocyte has been observed to the extent that the resulting halves could be seen to be separated only by a relatively very long and very fine connecting thread,

which was finally lost sight of; but a complete division could not be stated to have been seen in this case, and other observations point to the formation of long protoplasmic connexions between the leucocytes of the oyster as a repair phenomenon somewhat equivalent to the clotting effect of blood in vertebrates. The cultivation of the leucocytes of the oyster may nevertheless be possible, since Carrel and Burrows and later workers have shown that even specialised tissues of vertebrates can be grown outside the body in media and under conditions now well-known. A successful cultivation of the leucocytes of the oyster would undoubtedly suggest methods of attacking the problem of the cultivation of human leucocytes outside the body under known conditions and to yield known properties in the leucocytes. The potentialities of human leucocytes cultivated under such conditions may be so great that sufficient excuse is provided for any speculation which may point even faintly to a method by which such a desirable product may be attained.

Periodical Phenomena in the Temperature Functions of Certain Properties of the Metals.

IT is well known that the assumption of a quantum distribution of the energy of vibrations of the atoms in solids can be used to explain changes of the specific heat and other properties at low temperatures. Now this quantum distribution also seems to reveal itself in a more direct manner.

I have measured, partly in collaboration with Mr. F. Gunneson, the thermoelectric force at the ordinary temperature of specimens of iron and tungsten that had been successively heated at different temperatures and each time rapidly cooled. The thermoelectric force taken as a function of the heating temperature shows periodical changes, and I could easily distinguish certain repeated intervals of transformation. The approximative absolute temperature, T_n, of transformation, satisfies the relation $T_n = A \cdot n$, where A is a constant and n an integer number. This relation has been verified experimentally for iron from $n=3$ to 12, and for tungsten from $n=4$ to 9. The mean value found for A was for pure iron 97° and for tungsten 82°.

As remarked above, this phenomenon is most probably due to the quantum distribution of vibration energy. As the mean number of quanta of the atoms, however, increases continually with the temperature, I have assumed, to explain the periodicities, that the transformations occur at every temperature for which a certain fractional part $(1/r)$ of the atoms has a number of quanta like, or greater than, a new integer. This assumption gives $A = \theta/3 \log r$, where $\theta(=\beta\nu)$ is the characteristic temperature of the metal in consideration. From this relation r may approximately be calculated, though the values are, like those of θ, rather uncertain. I found for iron $r=4{\cdot}6$, and for tungsten $r=3{\cdot}3$. Thus the critical fractional part is about one-fourth, which seems to be a reasonable value.

Observation of Comets.

Dr. Crommelin in his valuable "Comet Notes," *B.A.A. Journal*, March 1922, p. 198, speaking of Reid's comet (1922 *a*), says "the comet must have been quite well placed for Northern observers last October and November, being of the 9th magnitude." It seems that Mr. Reid discovered the comet only a short time before it passed out of sight. This incident reminds us of the fact that a considerable number of these objects must escape observation altogether owing to the want of observers. It is remarkable that English astronomers appear hitherto to have taken little interest in cometary work, and that very few comets have been discovered from this country.

This is a regrettable circumstance. Yet the discovery and observation of comets include a comparatively easy and very attractive field of work open to amateurs with moderately powerful instruments. There are a great number of telescopic observers in the United Kingdom who have the means and the time at their disposal to accomplish valuable work in this department if they would only engage in it in an earnest manner. It is a branch which offers special inducements to amateurs, and holds out a greater prospect of brilliant success than perhaps any other sphere of labour. It is hoped, therefore, that some enthusiasts will turn their practical attention to it, for it is fair to suppose that some of them would like to follow in the footsteps of Messier and Pons, and the equally famous modern discoverers of comets, Barnard and Brooks.

The cometary section of the B.A.A. could not have a more capable director than Dr. Crommelin, and it would strengthen his hands, provide material for his researches, and repay him for his labours if the members of the section notified him of their discovery of one or two comets every year.

A Proposed Laboratory Test of the Theory of Relativity.

I SHOULD like to comment on the assumption as to the atomic weight of RaG made by Dr. King in his letter in NATURE of May 6, p. 582. Instead of taking this as known, and calculating the atomic weight of radium by taking account of the α-particle, energy and electron masses, it appears to me that the reverse process would be more justified. It is true that there is an unexplained discrepancy in the difference between the atomic weights of uranium and radium, but we have no reason to doubt the value of the atomic weight of radium obtained by Hönigschmid. As his radium was obtained from Joachimstal pitchblende, which contains practically no thorium, there is no liability to disturbance from the presence of isotopes of radium in his material. On the other hand, the theoretical atomic weight of RaG was obtained by subtracting the mass of five α-particles from the atomic weight of Ra. That the lowest value (206·046) found by Hönigschmid for lead from Morogoro pitchblende agrees so nearly with the theoretical value (205·93), shows only that the amount of original lead present in this material was very small, although, of course, it gave splendid confirmation to the theory of isotopy. We cannot say, however, that we are dealing with *pure* RaG, even though we know that the amount of admixed isotopes must be very small.

In dealing with such small corrections to the atomic weight as are involved in Dr. King's letter, it thus appears unjustifiable to start off by assuming that the atomic weight of RaG is 206·00. As Dr. King suggests, however, when the technique of the determination of mass spectra has developed, we shall be independent of admixed isotopes, and the problem will then be put to a rigorous test.

Artificial Disintegration of the Elements.[1]

By Sir Ernest Rutherford, F.R.S.

Absorption Curves in Nitrogen and Aluminium.

The variation in the number of scintillations as the absorption in the path of the rays increases from 10 cm. is shown in Fig. 1. The source of α-rays is in

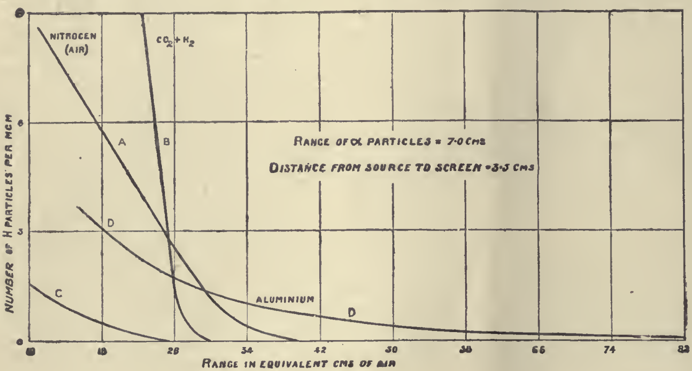

Fig. 1.

all cases radium-C. Curve A shows the effect in nitrogen (air) where the maximum range is 40 cm. Curve B is the corresponding absorption curve for a mixture of hydrogen and carbon dioxide, about 1 volume of hydrogen to 1·5 of carbon dioxide, which gives the same stopping power as air for α-rays. The number of scintillations due to hydrogen is very great in this case for absorptions less than 20 cm., but falls off rapidly, and none could be distinguished beyond 30 cm. Curve C gives the natural effect when the air is replaced by dry oxygen. This is small compared with that observed in nitrogen. Curve D shows the effect when an aluminium plate of 3·5 cm. stopping power is placed over the source and the air replaced by oxygen. Thus the particles liberated from aluminium are able to penetrate a much greater thickness than the particles from hydrogen or nitrogen.

It is a matter of great interest to find how the absorption curves for these long-range particles vary with the velocity of the bombarding α-particles. This has been examined for two typical elements, nitrogen and aluminium, and the results for the latter are shown in Fig. 2. It was found that to a first approximation the maximum range of the particles liberated from an element was proportional to the range of the bombarding particles. In all cases, the number of scintillations falls off rapidly as the velocity of the α-particles is decreased. The effect of velocity is specially marked in aluminium, and few, if any, particles are observed when the range of the α-particles is reduced to 4·9 cm. of air. The effect shown in curve D (Fig. 2) is due almost entirely to the "natural" scintillations from the source. When we remember that the decrease in velocity corresponding with the reduction of the range of an α-particle from 7 cm. to 4·9 cm. is only 11 per cent., we see how rapidly the number falls off with lowering of the velocity. It seems likely that no disintegration can be effected in the case of aluminium if the velocity of the α-particle falls below a certain critical value. This is not easy to prove conclusively, but, if correct, it indicates that the α-particle must have a certain critical energy to release an H-atom from the nucleus.

A very striking result was observed in the case of aluminium. It is to be expected that the liberated particles should for the most part be projected in the direction of the bombarding α-particles. Actually, it was found, however, that nearly as many were shot in the backward as in the forward direction. No evidence of such an effect was observed in the case of the nitrogen particles. The other elements have not yet been examined from this point of view, but we should expect an element like phosphorus, which gives

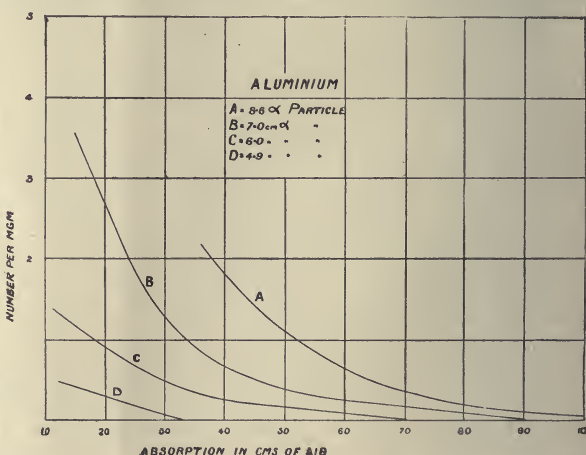

Fig. 2.

rise to long-range particles, to show a similar effect. A possible explanation of this striking result will be given later.

Nature of the Expelled Particles.

It can be shown readily that the long-range particles

[1] Continued from p. 586.

liberated from the elements are deflected by a strong magnetic field. By the adoption of special methods, it has been found possible to compare the amount of deflexion of these particles with that shown by the swift H-atoms produced when α-particles pass through ordinary hydrogen. It was found that the particles from nitrogen were deflected to about the same extent as the H-particles from hydrogen, and behaved in all respects like swift H-atoms carrying a positive charge. It seemed likely from the first that the corresponding particles from fluorine, phosphorus, and aluminium would also prove to be H-atoms liberated from the nuclei at speeds depending on the nature of the element and the velocity of the impinging particle. This has been confirmed in recent experiments by Dr. Chadwick and myself by a method similar to that employed for nitrogen. The bending of the particles in a magnetic field was determined for an absorption greater than 32 cm. of air, in order that the experiments should not be complicated by the possible presence of hydrogen contamination in the material under examination. The experiments were not easy on account of the small number of particles present under the experimental conditions and it was found necessary to devise a special microscope with a large field of view to carry out the investigation. The experiments were all in accord with the view that the particles from fluorine, phosphorus, and aluminium are swift atoms of hydrogen, and we may conclude that in each case an H-atom is liberated from the nuclei of these elements.

The maximum speed of ejection of the H-atom from the different elements can be estimated approximately by assuming that the law connecting the velocity and range of the α-particle holds also for the H-atom, namely, that the velocity is proportional to the cube root of the range. It has been calculated, and also confirmed by experiment, that the maximum speed communicated to a free H-atom by a head-on collision with an α-particle of velocity V is $1{\cdot}6V$, while its range in air is about 28 cm. Consequently, the maximum velocity of the H-atom from nitrogen, which has a range 40 cm., is $1{\cdot}8V$, and that from aluminium, with a range of 90 cm., $2{\cdot}37V$. The α-particle communicates 0·64 of its energy to a free H-atom in a direct collision, and it can be calculated that all H-atoms which have a range greater than about 56 cm. are projected with energy greater than that of the bombarding α-particle. In the case of aluminium, the maximum energy of the H-atom is 1·4 times that of the incident α-particle. This is a very interesting result, showing that in some cases there is actually a gain of energy as a result of the disintegration of the aluminium nucleus. We must therefore conclude that at any rate for all collisions in which the liberated H-atom has a range greater than 56 cm. of air, a part of the energy of the H-atom is derived from the disintegrated nucleus. This is analogous in some respects to the well-known gain of energy in the escape of an α-particle from a radioactive nucleus.

It must be borne in mind that the amount of disintegration effected by the α-particles is on an excessively minute scale. When a particle from radium-*C* passes through aluminium, it probably passes through the electronic structure of about 100,000 atoms, but only about two α-particles in every million get near enough to the inner nucleus to effect the liberation of an H-atom. We know that the collected α-particles from 1 gram of radium give rise to 163 cubic mm. of helium per year. If we suppose that all the α-particles from 1 gram of radium were fired into aluminium, the amount of hydrogen liberated by the disintegration of the aluminium nuclei could not be more than 1/1000 of a cubic millimetre per year. The amount of hydrogen liberated under possible experimental conditions is thus almost beyond the means of detection by ordinary chemical methods. It has only been possible to study the disintegration by the use of such a delicate method that each H-atom set free produces a visible scintillation on a zinc sulphide screen.

Mechanism of Disintegration.

From a study of radioactivity, it has been surmised that the α-particle or helium nucleus of mass 4 is one of the units of which the atoms are built up. The experiments referred to in this lecture gave the first definite proof that the hydrogen nucleus also is one of the units of the structure of some of the lighter elements. It is of interest to note that H-atoms are only liberated from elements the atomic masses of which are given by $4n+2$ or $4n+3$, where n is a whole number. Elements like carbon and oxygen, the atomic masses of which are given by $4n$, are not affected. This is shown in the following table :—

Element.	Mass.	$4n+a$.
Boron	11	$2\times4+3$
Nitrogen	14	$3\times4+2$
Fluorine	19	$4\times4+3$
Sodium	23	$5\times4+3$
Aluminium	27	$6\times4+3$
Phosphorus	31	$7\times4+3$

This result is to be anticipated if the nuclei of these elements are built up of helium nuclei of mass 4 and hydrogen nuclei. In order to account for the liberation of an H-atom from these elements, it is natural to suppose that the H-nuclei are satellites of the main nucleus. If the satellite is not too close to the latter, the α-particle in a close collision is able to give the satellite sufficient energy to allow it to escape from the system. It is to be anticipated that the H-satellites are closer to the nucleus in the case of aluminium than in the case of nitrogen, and that consequently more energy is necessary in the case of aluminium to effect their release. It is of interest to note that the chance of liberating a swift H-atom from nitrogen is not more than 1/20 of the chance of setting a free H-atom in corresponding motion. This indicates that it is probably only within certain prescribed limits of velocity of the satellite and position with regard to the central nucleus that the liberation of the satellite is possible.

We have already referred to the fact that the H-atoms from aluminium appear to be released in all directions. Actually, however, the velocity in the backward direction of the α-particles is distinctly less than in the forward direction. Such a result at first suggests that the α-particle acts the part of a detonator to the aluminium nucleus and that the energy of the escaping fragments is mainly derived from the nucleus. I think, however, that the following explanation is more probable and in better agreement with experiment.

If we suppose that the H-satellite is describing an orbit round the central nucleus, the direction of escape will depend on the relative position of the α-particle and nucleus at the moment of the close collision with the satellite. In the collision shown in

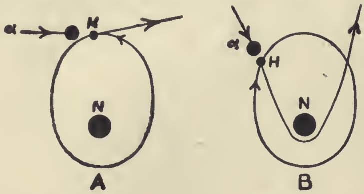

FIG. 3.

Fig. 3, *A*, for example, the H-atom will escape in the forward direction of the α-particle; in the collision (Fig. 3, *B*) the H-atom will describe an orbit round the nucleus and escape in the backward direction. The velocity imparted to the residual nucleus in the forward direction is much greater in the latter than in the former case. Such a view assumes that the forces between the positively charged satellite and nucleus are attractive instead of repulsive very close to the nucleus. This change of sign of the forces seems very probable at short distances from the nucleus, for otherwise it is difficult to understand how a positively charged complex nucleus can hold together.

Another consequence of some interest follows from the possibility of releasing H-atoms from light elements. It is generally supposed, although it is very difficult to obtain direct proof, that the helium nucleus is composed of four hydrogen nuclei and two electrons. In this combination there is a loss of mass, and this is ascribed to the very close combination of the structural units. On modern views of the relation between mass and energy, it follows that the energy liberated in the formation of a helium nucleus is more than three times the energy of the swiftest α-particle from radium. We should consequently not expect to be able to break up a helium nucleus with an ordinary α-particle, and this is in agreement with experiment so far as it has gone. In fact, the helium nucleus would appear to be the most stable of all nuclei.

Since, however, in the case of nitrogen, for example, we are able to release an H-atom by means of a slow α-particle, it seems clear that the H-satellite is not bound nearly so closely in the nitrogen nucleus as in the case of the helium nucleus. The change of mass due to the emission of energy in binding the H-satellite should consequently be much less than in the case of helium. The mass of the satellite should not differ much from the free H-nucleus of mass 1·0077 in terms of $O=16$.

If it be supposed that the nitrogen nucleus, for example, is made up of three helium nuclei of total mass 12 and two hydrogen nuclei, the mass of the nitrogen atom should not be exactly 14·00, but more nearly 14·01. In the case of the light elements, it appears probable that the effective mass of the protons composing the nuclei will vary in different atoms from about 1·007 to 1·000, depending on the closeness of the combination. Consequently, we should expect that the whole number rule found by Aston, which appears to hold for atomic masses to about 1 in 1000, would be departed from if measurements could be made with still further accuracy.

The next question which arises is whether any other particles beside that of hydrogen can be released by α-ray bombardment. Some time ago, I found that when radium-*C* was used as a source a small number of bright scintillations were observed, which had a maximum range in air of about 9 cm. It was natural at first to suppose that these were due to a new type of α-rays from the radioactive source. The effect, however, of aluminium screens in reducing the range of these particles led me at first to believe they were generated in the volume of the gases used, namely, nitrogen and oxygen. By comparing the bending of these rays in a magnetic field with that of H-particles from hydrogen, I concluded that they must be atoms of mass about 3 carrying two positive charges. Later experiments have brought home to me the untrustworthiness of this method of fixing the source of the radiation on account of the marked variation in thickness of films of metal foil. Using a more direct and simpler method, I have recently convinced myself that, at any rate in the case of oxygen, the particles have their origin in the radioactive source and not in the volume of the surrounding gas. Under such conditions, the comparative method of estimating the mass of the particles is no longer trustworthy. While a large amount of experiment will be required to fix definitely the nature of the radiation, the general evidence indicates that it consists of particles of mass 4, which are projected from the source and represent a new mode of transformation of radium-*C*.

By the methods outlined we can hope to detect only particles which travel a distance greater than the primary α-particles. If, however, a disintegration of an element should occur in which a massive particle is liberated, it is quite probable that the latter may have a range shorter than the α-particle. To examine cases of this kind, we can utilise the beautiful method developed by Mr. C. T. R. Wilson for showing the trails of ionising particles. Some experiments of this kind by a modified method have been made by Mr. Shimizu in the Cavendish Laboratory. A number of photographs showing well-marked tracks near the end of the range of the particle have been obtained. Until, however, these photographs are accurately measured up and compared with one another, it is difficult to be certain whether or not these branching tracks can be explained by collisions of the α-particle with the nuclei of nitrogen or oxygen. It seems clear, however, that the nuclei involved can travel considerable distances through the gas before being absorbed. If a large number of photographs be taken, it should be possible to settle definitely whether any collisions involving the disruption of atoms occur and to determine the probability of their occurrence. This direct method of attack of the problem, whilst laborious, should give very valuable information on this point.

It appears not improbable that the α-particle may occasionally be able to disrupt a helium atom from a complex nucleus like carbon or oxygen, which are believed to be composed of three and four helium nuclei respectively. The fact that the mass of these atoms is nearly an integral multiple of the helium atom suggests

that the helium nuclei are bound together with much weaker forces than the H-components of the helium nucleus itself. If the structure of the complex nucleus, say, of oxygen is such that the α-particle may communicate a considerable fraction of its momentum and energy to a single component, we should expect such disintegration to occur. It is also possible that charged particles of mass about 2 or 3 may exist as secondary building units of the complex nuclei of some elements, but so far no definite evidence of their liberation has been obtained.

I have so far confined my remarks to the disintegrating effects of swift α-rays, but it is important to consider whether the swift β-rays or energetic γ-rays from radium are able to produce any effect. We have found that neither β- nor γ-rays appear to have the power of giving sufficient energy to a free H-atom in ordinary hydrogen to detect it by the scintillation method, and consequently still less should we expect these rays to liberate a swift H-atom from a complex nucleus. It is possible, however, that these agencies, and particularly γ-rays of very short wave-length, may be able to liberate an electron and lead in this way to a change of its atomic number. Unless, however, the resulting atom is unstable and breaks up with the emission of a swift particle of the α-ray type, it will be difficult to be certain of such transformations. It should be noted that Slater has shown that α-rays are able to excite some very penetrating rays in their passage through ordinary matter. There is some evidence that such high-frequency radiation can only arise from the nuclei of atoms. If this be the case, it may be possible that the α-rays in some cases lead to a liberation of a β-particle from the nucleus and a consequent transformation. This effect, however, must be on a very small scale.

Many attempts have been made in the past to test whether the ordinary atoms can be disintegrated by special agencies. The late Sir William Ramsay, with the characteristic instinct for choosing the best line of attack, made a number of experiments on the effect of the α-rays of radium on matter and concluded that he had obtained evidence of the production of neon from water and the liberation of lithium from copper. These conclusions have not been confirmed by subsequent investigators, and in the light of the experiments described in this lecture it seems very doubtful whether the amount of transformation, even if it occurred, would be sufficient to be detected by ordinary chemical methods such as were employed.

Many instances have been recorded of the appearance of helium in discharge tubes, and it has been suggested that helium is a product of the transformation of the electrodes by the action of the intense electric discharges. The most notable experiments in this direction have been made by Prof. Collie, but the subsequent detailed investigations by Strutt did not confirm his conclusions. It is exceedingly difficult to prove that the appearance of helium is not due to its occlusion in the electrodes and liberation by the intense heating of the discharge. Similarly, many observations have been made of the steady liberation of hydrogen from electrodes. Winchester, who examined this effect in detail with thin aluminium electrodes, found that hydrogen was released until the electrodes were entirely dissipated. It is very difficult to believe that this hydrogen is a product of the transformation of aluminium when we remember the great energy of the α-particle required to effect it. As in the case of helium, it seems more probable that the hydrogen was originally absorbed in the electrodes.

While it is unsafe to be dogmatic on these points, the general evidence indicates that the atoms as a rule are such stable structures and the nuclei are held together by such powerful forces that only a most concentrated source of energy, such as the α-particle, is likely to be effective in an attack on such well-protected structures. Even when disintegration takes place, it is on an exceedingly minute scale, and only a few α-particles in a million are effective. If we had charged atoms available of ten times the energy of the α-particle from radium, we could probably penetrate the nuclear structure of all atoms and occasionally effect their disintegration.

Organisation for Visual Instruction.

By DR. C. W. KIMMINS, Chairman of the Cinema Education Committee.

A BULLETIN on the subject of visual instruction recently received from the University of Wisconsin is of great value as showing the remarkable results which have been obtained by the collection and distribution on an elaborate scale of material for the development of this method of teaching. The fact that in Wisconsin "the circuit plan of distribution" has been in operation for six years "with increasingly gratifying results," enables the authorities to speak with great weight on the subject. The Bulletin deals not only in considerable detail with every department of the organisation, but also gives valuable suggestions for overcoming difficulties such as the transport, storage, and repairing of films and lantern slides. An idea of the great importance attached to visual instruction by the University may be obtained from the fact that a room in the University extension building has been fitted up and equipped with stereopticons, motion-picture machines, and projection apparatus of many of the leading makes. Teachers and committees are invited to visit Madison at any time to inspect these machines side by side and compare their respective merits with one another. It is also possible at the same time to become better acquainted with the visual instruction plans and purposes of the university extension division as well as with the stock of material.

In the British Isles the useful part which visual instruction can play in educational methods has long been recognised, as is evidenced by the action of the more important local education authorities in providing the schools with lanterns, lantern slides, pictures, maps, diagrams, botanical and other specimens, and a variety of other material for this purpose. The Lantern Slide Committee of the London County Council has done valuable work for many years in the preparation of a magnificent collection of lantern slides suitable

for the illustration of lessons in various subjects. The catalogue of slides is frequently revised and ample provision is made for their distribution, of which full advantage is taken by the schools. The modern school, moreover, is generally equipped with a room, which is in constant use, specially designed for lantern illustrations. Thus, so far as the lantern is concerned, the schools have been generously treated.

The kinematograph film, however, is being used for educational purposes far more in America than in our own country. This is especially the case with adult education, in which the problem is an infinitely simpler matter than is that of the introduction of the kinema into the school for the normal purposes of instruction, in which a good case must be made for its value as against its competitor, the lantern.

There is no difficulty with propaganda films for various purposes, films dealing with general questions of health, those dealing with advanced science and specific industries, farming operations, general travel, and so on, provided always that they are prepared under the supervision of experts who are responsible for the sub-titles or captions. All are agreed on their value and great educational possibilities. They have, moreover, the advantage of being self-contained; each film tells its own, more or less complete, story. The difficulty begins when the film is used for continuous visual instruction in the general curriculum of the school.

The most promising feature of the situation as regards America is that the whole subject is being taken up by the universities, as is made abundantly clear by the Bulletin. The university extension division of the American university is a very important department, and being so intimately concerned with the extra-mural teaching of the adult, it comes into far closer personal touch with the schools than our own universities. The fact that in the Wisconsin experiment the majority of the films on educational subjects are edited by university professors is of far-reaching importance. The necessity for the collaboration of the expert and the film producer is emphasised in the Bulletin.

An admirable film was recently produced on a biological subject which would have much greater value and could be used with greater satisfaction if it were free from biological errors—errors that would not have crept in had its production been aided in and censored by men from the biology department of one of our universities. Illustrations could be multiplied almost indefinitely of films of the highest educational value that could be produced in the university and with the aid of the university staff.

What is generally known in this country as the educational film, suffers under the grave disadvantage of having to serve two purposes. It has to be of a sufficiently popular nature to be acceptable to the normal patron of the kinema theatre, and at the same time to contain sufficient material of scientific interest to appeal to the person who has a fair background of knowledge of the subject. To serve this dual purpose many beautiful films have been prepared at great cost to the producer, but they have not met with sufficient popular favour to stimulate the further production of this type of film. During the sitting of the Cinema Commission many teachers who appeared as witnesses said that the kinema might be used with great advantage in teaching such subjects as nature study and geography.

The difficulty of a dual purpose to be served has also been experienced in America, as is shown by the following extracts from the Bulletin:

(1) We therefore have two rather distinct classes of borrowers—the schools on one hand, calling for material to use in formal class-room work, and on the other civic and community organisations of many sorts, whose needs and desires differ from one another to a greater or less degree and in particular from the somewhat stereotyped needs of the schools.

(2) The class approach to the study of a topic through the aid of slides or motion-pictures should be essentially the same as a laboratory exercise in science. . . . In other words visual instruction should be reduced to a pedagogical method.

It will be seen by the above that whereas at present the ordinary educational film has only a limited usefulness in the schools in such subjects as nature study and geography, the more important problem of its value for normal school subjects by the production of a different type of film has yet to be solved. Many experiments are being made in the filming of well-known text-books and in the production of definite kinema text-books which may yield results of considerable value. Meanwhile, a very important original research is being carried out by distinguished experts in London, the report of which will soon be published and which will give much valuable information on some fundamental questions as to the relative value of the kinema and the lantern for teaching purposes.

There is, undoubtedly, in the kinema great educational possibilities, and the success of the important developments in visual instruction at the University of Wisconsin is a happy augury for the future.

Obituary.

ARTHUR BACOT.

ARTHUR BACOT, entomologist to the Lister Institute, died of typhus on April 12 at Cairo, where he was engaged in investigating the etiology of this disease and the precise method of its transmission through the agency of lice. His colleague Dr. Arkwright, working in the same laboratory, contracted the disease a few days later. His condition was the cause of grave anxiety, but he is now fortunately making a good recovery.

How they became infected is uncertain. They were occupied in experiments with lice that they had fed upon cases of typhus some time previously and had confirmed Nicolle's statement, hitherto unsupported, that the excreta of infected lice were capable of conveying the disease. Possibly they acquired the infection from such material. Experimental work upon typhus has already proved very costly, and Bacot's name is now added to the list of distinguished students, Conneff, Cornet, Jochmann, Luthje, v. Prowazek, Ricketts, Schussler, each of whom has fallen a victim to typhus while endeavouring to solve the problems of its etiology and epidemiology.

Bacot was born in 1866 and educated at Birkbeck

School. He did not enjoy the privilege of a scientific education, and on leaving school he became a clerk in a commercial house in the City, where he remained until forty-five years of age. Notwithstanding, his was a finely-trained scientific mind. Perhaps he was to the manner born. From boyhood he had been an enthusiastic entomologist, and despite his scanty leisure he became a lepidopterist of repute. Bacot was, however, no mere collector. Nor was he satisfied with observations and description of structure. It was the life history and bionomics of insects which attracted him and the use that could be made of entomology in the wider problems of heredity. He had an extraordinary knowledge of insects and a wonderful sympathy with them. Unfortunately his literary powers were slight, but his conversation on the subject of insect life was as fascinating as any of the writings of Fabre.

In the breeding of insects Bacot was extraordinarily successful, and some of the most important of his earlier contributions to entomological science were undertaken as studies in the laws of inheritance. Notable amongst these, which are scattered through the pages of the *Entomological Review* and the Proceedings of the Entomological Society, is his work with Prout "on the effects of cross breeding of different races of the moth *Acidalia virgularia*," which appeared in the Proceedings of the Royal Society, 1909.

The opportunity for Bacot to devote the whole of his energies to scientific work arose in the following way. The Commission for the study of plague in India having arrived at the conclusion that the essential means of spread of bubonic plague was the rat-flea, it was obviously advisable to obtain as much knowledge of the bionomics of these insects as possible. Bacot was invited to undertake the investigation. He was still occupied in clerical work, and at first he demurred on the score of both lack of time and lack of any special knowledge of fleas. His modesty was, however, overcome by the assurance that innocence of all but the external features of the siphonoptera was fairly general and the difficulty due to want of leisure was, to some extent, met by the provision of an assistant to carry out his instructions while he himself was at his office.

The results of eighteen months' work was highly satisfactory. The whole life history of the commoner rat-fleas was ascertained with great completeness, and the influence of all the significant environmental conditions upon their longevity and rate of propagation. The adverse effects of various treatments which might conceivably be used in combating plague were also determined. The observations formed the subject matter of a monograph on the bionomics of the common rat-fleas occupying 200 pages of the *Journal of Hygiene*. The work is a model of accuracy, clarity, and completeness, and at once stamped Bacot as an observer and experimenter of high quality.

The value of such a man to medical discovery was apparent, and in 1911 a special position was created for him at the Lister Institute, and he was invited to become its entomologist. He accepted the position, and henceforth was able to devote himself entirely to science and to apply his entomological knowledge and experimental skill to problems in epidemiology.

In the congenial atmosphere of the Institute, with well-equipped laboratories at his command, Bacot rapidly became expert with bacteriological and histological techniques, and was able to collaborate with his medical colleagues with completeness and to take a full share in the experimental work and in the responsibility for the results.

The Indian Commission had demonstrated fully that the agent of infection in the case of bubonic plague is the rat-flea, but the *modus operandi* it had been unable to determine. It was some years later (1913) that Bacot and Martin showed experimentally exactly how it occurred. From their observations, the very existence of plague seems to depend upon the accidental property of the plague bacilli of growing in the form of a coherent sticky mass. When the flea inflates its stomach with the blood of a plague-stricken rat, the bacilli, introduced with the blood, rapidly multiply in the alimentary canal, forming masses of culture. These masses increase quickly in size until they effectually plug the gizzard at the entrance to the stomach and grow forward in the gullet. A flea with its alimentary canal obstructed by this means suffers from a thirst which it is unable to quench, and bites with more persistence and much greater repetition than normally. The entrance into the stomach being obstructed, the efforts of the insect only inflate its œsophagus with the fresh blood, some of which runs back into the wound well dosed with plague bacilli, as soon as the action of the insect's pharyngeal pump ceases. What remains serves as culture media for plague bacilli to grow upon, and the result is, as Bacot was able to demonstrate by some wonderful sections, a flea contaminated, literally, up to its mouth. The plague bacillus passes no essential part of its life history in the body of the insect, such as is the case with the malaria parasite. It is an instance of spurious metaxeny, but a flea in the condition just described cannot fail to carry infection once it is let loose upon a susceptible animal.

In 1914 Bacot proceeded to Sierre Leone as the entomological member of a Yellow Fever Commission sent out by the Colonial Office. The original scheme of work was upset by the removal of the medical members owing to the war. Bacot, however, remained for one year and studied the bionomics of *Stegomyia fasciata*, the mosquito which is the transmitter of yellow fever, and produced a very complete and detailed monograph upon the life history of this insect in West Africa and the various conditions which modify its rate of propagation.

Bacot returned to England in August 1915 and at once threw himself into the intensive study of lice and the most practical method of ridding our soldiers of these vermin in view of their depredations and the incident dangers to health therefrom. The value of Bacot's work in this direction was great, and the experiments on which his conclusions were based were always made upon himself under conditions similar to those actually encountered in the field. The recommendations were soon found to be sound and practicable ones, and in 1916 he was asked to accept the position of honorary entomological adviser to the War Office. In this capacity he was constantly consulted by military sanitarians, who were bombarded with various nostrums and devices for dealing with the louse problem.

In 1915–16 our troops in France were found to be suffering from a new disease, "trench-fever," which soon proved to be a principal cause of medical invaliding.

McNee demonstrated that it could be transmitted from man to man by the inoculation of a small quantity of blood, and suggested that the usual manner of spread was by the agency of the innumerable lice infesting our soldiers. In 1917 a committee to study this new disease was appointed by the War Office with Sir David Bruce as chairman, and Bacot was invited to join as entomological member. The British Trench Fever Committee showed first that McNee's suggestion was correct and that this disease was transmitted by lice, a fact subsequently confirmed by the American Commission in France. In the course of their experiments Arkwright and Bacot confirmed the observation of Töpfer that minute pleomorphic bodies, of the order of magnitude 0·3 to 0·5 μ and somewhat similar to *Rickettsia prowazeki*, supposed by Rocha Limas and others to be the cause of typhus, were present in the gut of lice which had been fed upon patients suffering from trench fever. They failed to find them in lice with an unexceptional family history, brought up for generations by Bacot and nourished upon his own blood. Bacot studied the development of the little microbes in the gut of the louse day by day after its meal of infective blood, and he and his colleagues established that only lice in which these bodies were present were capable of transmitting trench fever. All attempts to cultivate the organisms have so far failed and the supposed causality of trench fever rests upon these observations of association.

Similar structures had been described by Ricketts and Wilder in 1910 in the gut of lice fed upon typhus fever cases, and later by Wolbach in the tissues of patients who had fallen victims to this disease. There was thus reason for supposing that the virus of both trench fever and typhus was of the same nature, and consisted of a new type of microbe which propagated in the tissue of the gut of lice and in the human body should it find access thereto.

Accordingly, when trench fever disappeared from this country, on the cessation of war, leaving many problems concerning it unsolved, Bacot turned his attention to typhus, as this disease presented analogies both as regards etiology and method of transmission. In 1920 he joined the Typhus Research Commission of the League of the Red Cross Society and went to Poland, taking with him a supply of his lice with a clean family history. He was responsible for the insect side of the investigation which, in view of the nature of the problem, was not the least important. The Commission, which has recently published its report, made many valuable observations. It was able to confirm under more rigid conditions of experimentation, earlier work which had been carried out in various parts of the world. The probability that *Rickettsia prowazeki* is the virus of typhus was thereby materially increased, but the labours of the Commission left the evidence resting upon association only.

In the course of work at Warsaw, Bacot accidentally infected himself with trench fever. Being in want of a further supply of lice for his experiments, he collected them from a public bath-house and nourished them upon his person. A sharp attack of the fever followed, and some of the insects were found to harbour the Rickettsia he and Arkwright had described in their work for the Trench Fever Committee two years previously. Afterwards, for some months, he was able to infect his clean stock of lice by feeding them on himself. Returning to London in the summer of 1920, with the collaboration of his colleagues Arkwright and Atkin, Bacot continued his endeavours to settle the matter of the virus of typhus. They were unfavourably situated in London to obtain a supply of typhus material. Consequently, when towards the end of last year an invitation came from the Egyptian Government to study the problem in Cairo, where typhus is endemic, the opportunity was welcomed. In company with Arkwright he proceeded to Egypt early in the year, and was soon installed in the excellent laboratories of the Department of Public Health, presided over by an old colleague, Dr. Charles Todd. The research was advancing with promise and his letters expressed enthusiasm regarding its progress. On March 24 he became ill and died on April 12.

Bacot had a passion for knowledge and a natural aptitude for scientific research. If the attainment of his quest promised to be of service to his fellow-creatures, this was an added attraction. He was well acquainted with the risks attending some of his work but, whilst never reckless, he was not a man to be deterred by danger from the pursuit of a useful inquiry. Its existence indeed appealed to a side of his nature which contributed to the charm of his personality.

His comrades at the Institute are proud of his attainments, but will rather remember him as a dear friend who was always helpful and was never known to be inconsiderate or unkind. C. J. M.

Louis Ranvier.

It must come as a surprise to many of the younger generation of biologists that Ranvier, whose name is immortalised in countless text-books, has but recently passed away. Born at Lyons in 1835, Louis Ranvier was attracted at the outset of his medical career to the study of histology, both normal and pathological. As concerns the minute investigation of the tissues, research and discovery were to all intents and purposes stagnant in France when the youthful Ranvier, full of indomitable zeal and unquenchable enthusiasm, devoted himself to the subject and determined that a study, the foundation stones of which had been laid by the great Frenchman, Bichat, should be worthily pursued. His early work was carried out in a small private laboratory which he equipped in the Rue Christine in Paris, where he and his friend Cornil not only taught the principles of histology to students but also produced, as a result of their joint efforts, the "Traité d'anatomie pathologique," a treatise which rapidly became classical.

Ranvier soon attracted the notice of Claude Bernard, who, recognising his great technical skill, enlisted his services for the College of France in 1867. He was soon put in full charge of a newly instituted Laboratory of Histology, where his reputation and fame grew so rapidly that a chair of general anatomy was created for him, into which he was installed in 1876. For a period of thirty years he was associated with the College of France, where he laboured with untiring zeal and where his most important discoveries were made.

The field covered by Ranvier's researches is exceed-

ingly wide. There is no tissue and scarcely an organ of the body which he did not investigate with characteristic thoroughness. Much of what is to-day sound knowledge of the structure of the connective tissues, glands, nerves, and nerve-endings, we owe to Ranvier. His discoveries in connection with the peripheral nervous system are perhaps the most familiar. It seems incredible that until Ranvier taught otherwise, a medullated nerve was thought to be a continuous tube. The term "nodes of Ranvier," by which he is best known, is most unfortunate. He described the interruptions in the contour of the medullated nerve as "étranglements annulaires." The term "node" is inexcusable and not to be condoned by its usage as an alternative in "constrictions or nodes of Ranvier," a solecism of which many writers are guilty.

Ranvier was not content with describing and delineating the minute structure of tissue or organ but ever sought to discover the functional interpretation of what he saw. Many of his investigations were to this end, and in this sense he must be regarded as the father of experimental histology. A master of technique, his manipulative dexterity was unequalled, and the laboratory practice of the present day is largely founded on his methods.

Ranvier's numerous writings are a model of clearness and exactitude. Never content with knowledge at second hand, he took such meticulous care to ensure accuracy that his statements are invariably trustworthy. His "Traité technique d'histologie" is undoubtedly the most original text-book on the subject ever written, and bears monumental testimony to his indefatigable energy and boundless resource.

Some twenty years ago Ranvier retired from a life of incessant labour to his country estate. Laboratory and scientific societies knew him no more; as he worked so he rested, revelling in the pleasures of a rustic life. Full of years and honour Ranvier passed peacefully away on March 22.

Current Topics and Events.

MUCH interest has been aroused by reports in the *Times* and other newspapers of the discovery of mummified animals in the Koster caves, 100 miles west of Johannesburg, South Africa. These caves are situated in a district in which numerous stone implements and other evidence of early human occupation have been found. They have therefore been carefully examined by Mr. Harold S. Harger, a well-known geologist, whose report is disappointing. It appears that the mummified remains occur in a thick layer of bat guano on the floor of the main cave, and represent only modern animals. It is not unusual to find such remains in the circumstances described, and there is one known case in Patagonia in which the skin and soft parts even of an extinct animal (a ground sloth) have been preserved. There is no doubt that the caves and surface deposits in the Koster district of South Africa are well worthy of the attention of the local geologists and anthropologists, but they have not hitherto afforded anything of special note.

A LARGELY attended meeting of physicians and others interested in mental hygiene was held in the rooms of the Royal Society of Medicine on Thursday, May 4, in order to inaugurate the new National Council for Mental Hygiene. The chair was taken by Sir Courtauld Thomson, who was afterwards elected first president of the Council. He communicated to the meeting a message of welcome from the National Council of Mental Hygiene of the United States, and expressed a hope that, by the establishment of the British Council, Great Britain would be able to take her proper place in the forthcoming international conference on the subject. He made a special appeal to laymen to join the new movement, so that they might co-operate with the medical profession in a common endeavour to improve the mental health of the country. Dr. Head insisted that mental hygiene is as important as sanitation, that mind and body are inextricably intermingled, and that no structural disease is free from mental change. We should have been spared, he believed, the recent exhibition of auto-suggestion in this country, if its people had been better educated in mental hygiene. Sir Leslie Scott alluded to the greater assistance needed by those administering criminal justice from experts in mental disorders. Other speakers included Sir Humphry Rolleston, Sir Frederick Mott, Dr. Farquhar Buzzard, Lord Southborough, Hon. Lady Darwin, Major-General Sir John Goodwin, and Sir Maurice Craig. The provisional committee was empowered to draw up a constitution and to elect an executive committee.

THE half-yearly council meeting of the National Union of Scientific Workers was held on Saturday, May 6, at the Caxton Hall, Westminster, Dr. A. A. Griffith, president, in the chair. The report of the executive committee was presented by its chairman, Prof. L. Bairstow, who mentioned the co-operation of the Union with the British Medical Association in regard to removing disabilities suffered by scientific institutions under the Key Industries Act, and with the Teachers' Registration Council on the subject of the danger of parsimony in education. Progress in the negotiations with the British Association of Chemists was reported, and a scheme outlined which it was hoped might be made the basis of an immediate temporary arrangement for joint working, to tide over the period until complete amalgamation could take place. Negotiations on behalf of members had been carried on with the Ministry of Agriculture, the Air Ministry, and the India Office, and satisfaction obtained on many points. The Union had also been in communication with the Inland Revenue Commissioners for the purpose of furnishing them with a typical schedule of expenses incurred by scientific workers in various branches of science with a view of obtaining definite rulings and further concessions. Report was made of the successful working of the Government Section committee, which had enabled members in the various depart-

ments to discuss their common problems and formulate a common policy, and resolutions were adopted calling for the formation of similar sections to represent members engaged in university and other educational work, and members in industry. The vacancy on the executive caused by the death of Dr. Lyster Jameson was filled by the election of Dr. J. Henderson Smith, of Rothamsted.

THE *Quest* with the Shackleton-Rowett expedition has arrived at South Georgia after a cruise in the Weddell Sea. Mr. F. Wild, who succeeded Sir E. H. Shackleton in command, gives a summary of the results of the voyage in the *Times* of May 5. As was anticipated, ice conditions in the Weddell Sea proved to be unfavourable this year. After leaving the South Sandwich group where Zavodoski Island, the most northerly point of the Traversey Islands, was explored and surveyed, a course was set eastward. The pack was entered on February 4 in lat. 65° 18′ S., long. 15° 23′ E. Two attempts to penetrate southward failed on account of heavy ice and the low power of the *Quest*. The positions reached were respectively lat. 69° 18′ S., long. 17° 11′ 30″ E., and lat. 69° 49′ S., long. 0° 1′ W., and mark approximately the points where Bellingshausen in 1820 was forced to turn back when seeking a route to the south. No new land was discovered by the *Quest* although the soundings indicated, as was expected, that it could not be far south of lat. 69° S. After the second failure to get south, the *Quest* turned westward across the Weddell Sea through heavy pack. The objective was Ross's "appearance of land" approximately in lat. 65° S., long. 44° W. This report, which dates from 1843, had never been actually disproved although subsequent expeditions to the Weddell Sea had made the existence of land in that locality extremely unlikely. The *Quest* was beset within 35 miles of Ross's "appearance of land," and escaped only with difficulty. There was no sign of land and the depth of the sea was 2446 fathoms. The *Quest* then sailed for Elephant Island and South Georgia. On April 18 the expedition was to leave for Tristan da Cunha, Gough Island, and Cape Town. The expedition has not succeeded in adding to our knowledge of Antarctic lands, but has done valuable oceanographical work. A line of soundings between South Georgia and the place where the pack was entered cuts across a practically unsounded region. The track across the Weddell Sea seems to follow the course of the *Scotia's* line of soundings in 1903.

IN the *Chemiker Zeitung* of April 15 it is announced that Prof. P. P. von Weimarn has been appointed Research Associate of the Imperial Research Institute of Osaka, Japan, and charged with the creation of a laboratory for research in colloids.

NOTICE is given by the Chemical Society that applications for grants from the Chemical Society Research Fund must be received, on the forms provided, on or before Thursday, June 1.

ON Tuesday next, May 16, Prof. W. Bulloch will begin a course of two lectures at the Royal Institution on "Tyndall's Biological Researches" and "The Foundations of Bacteriology." These are the Tyndall Lectures. The Friday evening discourse on May 19 will be delivered by Sir William Bragg on "The Structure of Organic Crystals."

APPLICATIONS are invited by the Salters' Institute of Industrial Chemistry, Salters' Hall, St. Swithin's Lane, E.C.4, for a limited number of fellowships, each of the annual value of 250*l.*, falling vacant in October next. Applications, with full particulars of training and experience, must reach the Director of the Institute before June 10.

THE Board of Trade has received formal notices of complaint that boric acid and metaldehyde have been improperly included in the lists of articles chargeable with duty under Part I. of the Safeguarding of Industries Act, and that gallic acid and "R" tannic acid have been improperly excluded from these lists. These complaints will be submitted to the Referee, and persons directly interested should communicate with the Assistant Secretary, Board of Trade (Industries and Manufactures Department), Great George Street, London, S.W.1.

THE list of papers bearing upon the zoology, botany, and prehistoric archæology of the British Isles, issued during 1920, which has been prepared by Mr. T. Sheppard and published in the Report of the British Association for 1921, is now available as a separate pamphlet. The list occupies fifty pages of close print and is divided into three sections, zoology, botany, and prehistoric archæology. In this form it should prove very useful to students and workers. The list of papers is very complete, and as a guide to the work done in the British Isles it will be invaluable to workers in systematic natural history and to those responsible for regional surveys. Copies may be obtained, we understand, at the offices of the British Association.

THE Zoological Society has acquired by purchase two reindeer from Norway for its collection. During March 157 additions to the menagerie were received, 61 by presentation, 20 deposited, 70 by purchase, 2 by exchange, and 4 born in the gardens. The most interesting of the new acquisitions are two tree porcupines from Canada, three Alpine marmots from southern France, and a black-gloved wallaby from W. Australia. An Indian kestrel from Darjeeling is new to the Society's collection. At the monthly meeting of the Society on April 19, thirty-five new fellows were elected and forty candidates proposed for membership.

THE celebration of the centenary of the Royal Astronomical Society will begin on the evening of Monday, May 29, with a Conversazione, to be held, by kind permission of the Royal Society, in their rooms, at Burlington House. The following morning will be devoted to an introductory address by the president, Prof. A. S. Eddington, one on the history of the society by Dr. Dreyer, and a biographical address, with portrait slides, by Prof. Turner. In the afternoon there will be a scientific meeting, at which associates of the society present will be invited to speak on their work. A dinner will be held in the

evening. On Wednesday, May 31, fellows and associates have been invited by the president and council of the British Astronomical Association to attend the meeting of the association, at Sion College, Victoria Embankment, and on Saturday, June 3, there will be a visit to Greenwich Observatory, by invitation of the Astronomer Royal.

EARL BUXTON'S comments, at the annual meeting of the Royal Society for the Protection of Birds, on the ways and methods of the modern egg-collector, have made something like a sensation in the ornithological world, focussing and expressing, as they do, a feeling of protest strong among the majority of bird-students against the wholesale and reckless collection of wild birds' eggs in clutches by certain "oologists." The text of that part of Lord Buxton's speech is published in the spring number of *Bird Notes and News*, from which it appears that for the purpose of so-called science the successive layings of certain birds for an entire season are sought in various parts of the country, by the collector and his agents, regardless of the comparative rarity of the species, and also, it would appear, of Bird Protection Orders. Lord Buxton's subsequent correspondence with representatives of the British Ornithologists' Union will appear in the Society's annual report. The pages of *Bird Notes and News* are doubled in number with the present issue, the first of its tenth volume and twenty-first year.

THE Bulletin of the South-Eastern Union of Scientific Societies announces that the twenty-seventh Annual Congress of the union will be held at Southampton, on June 14-17, inclusive. The new president, to be elected at the evening meeting of the first day, is Col. Sir C. F. Close, who will give an address on "Small Rivers as Sources of Power: with special reference to the River Itchen." Archæology, botany, geology, and physiology will be represented in the papers and lectures which will be delivered at the Congress, and the programme which has been prepared should prove a very comprehensive and interesting one. At a recent council meeting an Archæological Section of the union was authorised, and Sir Edward Brabrook, Dr. W. Martin, and Mr. H. Norman Gray were appointed to deal with its development, with power to act. The council has also authorised the formation of a Zoological Section, and the carrying out of the initial steps have been entrusted to Prof. E. B. Poulton, and Messrs. R. Adkin, H. J. Turner, and Stanley Edwards.

THE next International Conference of Pure and Applied Chemistry will be held at Lyons on June 27-July 2, and as usual a variety of topics of interest to chemists will come up for discussion. The former International Committee on Atomic Weights has now, in consequence of the recent work on isotopes, become an International Committee on the Elements, and the British representatives are Prof. Soddy and Dr. Aston; another committee is considering a uniform system of abbreviations and a third is dealing with the preparation of research chemicals. The Federal Council for Pure and Applied Chemistry has asked Mr. F. H. Carr to act as correspondent for this committee. Mr. A. Chaston Chapman is acting as correspondent, in conjunction with the Society of Public Analysts, in connection with a project for the standardisation of food analysis, and Dr. Mellor has been appointed to put forward the views of British chemists in relation to ceramic matters. Most countries which are represented at these conferences have a fund from which the expenses of the delegates can be paid. Great Britain is an exception, and the Chemical Society has in a very public-spirited manner agreed to pay the travelling expenses of two of the delegates from this country. Some other bodies should follow this excellent example in order that Great Britain may take an adequate part in the regulation of those chemical matters which are capable of international treatment. To meet together in foreign parts, making the acquaintance of chemists from divers countries and comparing notes, helps to advance knowledge. *Plurimi pertransibunt et augebitur scientia*, as the Vulgate puts it.

Our Astronomical Column.

THE PLANET MERCURY.—Mr. W. F. Denning writes that the most favourable time of the present year for viewing this object will occur between May 12 and 27. Mercury is rarely visible to the naked eye, and intending observers should utilise the present opportunity of catching a glimpse of the fugitive little object, which it is recorded always evaded the eyes of Copernicus. The planet will be at its greatest apparent distance from the sun on May 23 and will set about two hours after the sun for about a fortnight. It will be easily visible to the naked eye near the west-north-west horizon, at about 8.40 P.M. G.M.T. if the sky is clear in that region. Twilight will be very strong but Mercury may be seen with a rosy fluctuating light rather brighter than that of a first magnitude star. It may be easily identified, for the bright planet Venus will be not more than four or five degrees to the eastward, and situated to the left and above the smaller orb of Mercury.

ADVANCES IN ASTRONOMY.—The presidential address to Section A at the Durban meeting (1921) of the South African Association for the Advancement of Science contains a good *résumé* of the remarkable advances in stellar astronomy during the last half-century. The treatment is full and explicit, and includes Dr. Shapley's investigations on the globular clusters (not, however, the recent criticisms of his conclusions) and the remarkable results obtained with the Mt. Wilson interferometer, both in investigating close binaries, such as Capella, and in measuring the angular diameter of the giant red and orange stars.

Many personal details of the donors and the designers of the great American telescopes are given; as a contrast Airy is quoted as saying in 1832 that no public observatory existed in the United States. The address concludes by expressing the hope that the development of university education in South Africa will lead to a corresponding expansion of astronomical observation and discussion, and the conviction that such studies draw out all that is highest and best in the human intellect.

Research Items.

Mexican Archæology.—Since the days of the Spanish occupation, the neighbourhood of Mexico City has supplied a rich field for the exploration of the antiquities of the pre-Columbian period. The most important problem to be solved is the investigation of the strata showing the succession of cultures —the Archaic, Toltec, that is pre-Aztec or Teotihuacan, and Aztec. Some progress in this direction is outlined in a report by Mr. A. M. Tozzer, published in Bulletin 74 of the Bureau of American Ethnology. It is at present impossible to determine with exactness the demarcation between the Toltec and Aztec cultures, the inference being that the former flourished towards the end of the first millenium A.D., and their influence in Yucatan, at least, extended into the fifteenth century. The artifacts discovered belong principally to the Toltec culture, those of the Aztec period being few in number and relatively unimportant, while a few things which are clearly pre-Toltec or Archaic were encountered. It is interesting to record that the methods of scientific archæology are being applied to this area, with expectations of important discoveries in the near future.

Fossil Man.—The Trustees of the British Museum have just issued a third edition of the useful little "Guide to the Fossil Remains of Man in the Department of Geology and Palæontology in the British Museum (Natural History)." The guide was first prepared on account of the interest in the study of fossil man which had been aroused by the discovery of the Piltdown Skull, and, as an introduction to the specimens and casts exhibited, described the main conclusions bearing on the question of the evolution of man which are furnished by palæontology, geology, and anthropology. In the third edition, the later part of the guide has been rewritten and extended to include an account of the skull found in the Broken Hill Mine, Rhodesia, in 1921, and two plates giving four aspects of the skull have been added. The more remarkable features of the skull are briefly described, and the chief points in which it presents similarities to the anthropoids, Neanderthal man, and modern man are noted. As regards the question of antiquity, it is pointed out that the life of the southern hemisphere has been less progressive than that of the northern, and the discovery of primitive species of man in comparatively modern deposits was to be expected. After summarising the evidence it is concluded that either the accumulation of animal remains in the cave is modern compared with deposits left by palæolithic cave men of Europe, or the animal life of Rhodesia has changed more slowly than that of Europe.

Geology in New Zealand.—Prof. J. Park reviews the structure of New Zealand in the Transactions of the N.Z. Institute, vol. liii., 1921, a publication that includes several papers on geology. As seems usual in that enterprising and fortunate dominion, the illustrations are of very fine quality. Brother Fergus (M. J. Gilbert) describes the unconformable series of the Waikato Heads district, where an "older-mass" terminating in the post-Jurassic peneplain is capped by a "younger-mass" of undetermined Cainozoic age. Mr. J. A. Bartrum revises the geology of Great Barrier Island, which guards the Hauraki Gulf on the long promontory of the North Island; he has discovered a large area of delicately banded Cainozoic rhyolites, previously described as slates and sinter. Dr. C. A. Cotton's account of the warped land-surface near Port Nicholson, the harbour of Wellington, is written with a true geographic instinct.

The Galician Petroleum Industry.—On April 11, a paper on "Galicia and its Petroleum Industry," by Mr. Albert Millar, was read at the Institute of Petroleum Technologists, in which was embodied technical and economic information of interest and importance. The most important area at the present time is still that of Boryslaw-Tustanowice-Mraznica, this being the district of the largest producing wells during the last fifteen years. As is well known, however, there has been a steady decline in production latterly, both in this area and in Galicia as a whole. While this causes alarm in certain quarters, it has been the means of promoting the development of new fields, chiefly those of Hordyscze, Ratoczyn, and Opaka, in the Tustanowice district; deep drilling at Popiele and Jasienica, north-east of Boryslaw, has also been undertaken. The bulk of the oil, which is of high grade and has a paraffin base, has hitherto been obtained from Oligocene beds, together with a smaller quantity from Eocene deposits. The Cretaceous rocks, petroliferous in Western Galicia, are largely an unknown factor as regards their ultimate commercial value, as they have been penetrated only by a few wells in the main region, and the results were inconclusive. Many experts believe that water troubles will prove more formidable at the Cretaceous horizon than is the case in the younger sands. Unquestionably water is the greatest difficulty to contend with in Galicia, and the calamitous experiences at Tustanowice, where "200 ton" wells were rapidly watered, have done much to inspire misgiving as to future prospects. Emulsification up to, and in some cases more than, 20 per cent., has resulted in special methods being devised for separating the oil. Zuber believed this water to be the indication of exhaustion of the field, but later observers favour its localisation to Eocene sands. Gasoline extraction, started in 1914, has made much headway, 660,000 klg. being obtained last year, a record production for Galicia.

A New Method of Gauging the Discharge of Rivers.—The method of gauging discharge based on the principle underlying chemical hydrometry has been in use for some time. It depends on the liberation of a known quantity of salt in solution into the river at a known rate and the estimation of the amount of salt in the river some distance below the inlet of the salt solution. This method has been proved to give very accurate results, but its chief disadvantage is the cumbersome nature of the preparations involved, not to speak of the cost. In the Scientific Proceedings of the Royal Dublin Society for April, Prof. J. Joly describes a method of utilising the same principles which gives even more accurate results and is very economical in labour and money. Radioactive measurements can be made with great accuracy by a simple form of electroscope. In the place of salt, which has to be introduced into the river by the hundredweight, a few litres of a solution containing a trace of radium is sufficient. Prof. Joly proposes to use pitchblende dissolved in nitric acid and then diluted with water. The solution is fed into the river under constant pressure. The water samples when collected are conveyed back to the laboratory and stored in ordinary boiling flasks for ten or twelve days. The emanation is then boiled off into a small exhausted bulb, from which it is introduced into the electroscope. At the end of three hours the electroscope is read and the river discharge can then be deduced.

Science in Bohemia.

By PROF. BOHUSLAV BRAUNER, Bohemian (Charles') University, Prague.

THE years during the war and after were not very favourable to our scientific investigations. The grants for the scientific institutions were reduced by the late Austrian Government in the same degree as the prices of instruments, etc., increased; many a young man of science has left the High Schools and never returned again. We are now enjoying the fourth year of our liberty and independence, but our country was bled by Austria, so that in order to keep our liberty, which we owe to the magnanimous support (moral only, alas!) of the Allied Powers, our Republic had to start its life from the very beginning. Paper and printing became so enormously expensive that the two chief scientific societies, the Royal Society of Bohemia, founded in 1770, and the Bohemian Academy of Science and Art, founded 1890, are able to print only very short scientific communications.

FIG. 1.—Central Hall of the old University Library, Clementinum, Prague.

I beg, therefore, to place before English men of science a very condensed account of the most prominent papers published during the last few years by Bohemian men of science. (Our German countrymen publish their scientific papers in Germany or in Vienna—as before the war.)

ASTRONOMY AND ASTROPHYSICS.—With the 8-inch telescope of the Observatory of the University no important work can be done. Prof. Brauner refers to a communication published in NATURE of April 8, 1909 (vol. 80, p. 158), entitled "The Gases of the Ring Nebula in Lyra," in which he showed that of the four gases, separated by rotation as visible from Th. Wolf's spectra, the innermost gas ($\lambda=460$) must be lighter than hydrogen, whereas the outermost gas D ($\lambda=373$) will have a density between that of hydrogen and helium. We know to-day that the densities of the gases hydrogen and helium in nebulæ are proportional to their atomic weights. The line $\lambda=469$ in the gas A is now generally regarded as a line in the principal series of helium and identical with the line $\lambda=4685{\cdot}90$ obtained by Fowler by condensed spark discharge, but other helium lines, especially $\lambda=5876$ (10), are missing, and so the gas is called "protohelium." That the line $\lambda=373$ or $\lambda=3726{\cdot}1$ and $\lambda=3728{\cdot}838$ really corresponds to a gas heavier than hydrogen and lighter than helium was proved by Bourget, Fabry and Buisson, who found in 1914 that its density is 2·74, whereas Nicholson calculates 2·95.

METEOROLOGY.—After the Austro-Hungarian Empire went to pieces it became the duty of the young Czechoslovak Republic to establish an institute that would take charge in its territory of the stations that were previously under the agency of the Vienna and Budapest central meteorological offices. At the beginning of 1920 the Board of Education established the State Meteorological Institute (Prague II. U Karlova 3.), the first duty of which was to re-examine the list of the stations that suffered badly during the war. The central office is now running 120 stations, of which four are first-class observatories, Prague, Milešovka (mountain station, elevation 2550 feet), Brno and Stará Dala. To the central office more than 20 stations send their observations daily, and a report of these is dispatched by "radio" three times daily from Prague. Monthly reviews of the weather are published meanwhile for the whole Republic and the climatography of the country is being prepared. The credit for this important work is due to Prof. Hanzlík and Director Schneider.

PHYSICS.—This science does not possess any long tradition in Bohemia, for the first really modern physical institute was built by Prof. Strouhal—who is known for his work "On Steel" carried out with Prof. Barus forty years ago—only in the first decade of this century. His successor was Prof. Bohumil Kučera, whose early death in 1921 is lamented. His principal work was on radioactivity. This highly talented physicist, a good English scholar, was preparing a text-book on mechanics for English students. Prof. Posejpal is working chiefly on the dependence of the refraction of gases on their pressure. Prof. Macků, one of our best physicists, is studying the oscillation of 2 and 3 conjugated circles. Another promising young physicist is Prof. Žáček, who investigated the influence of the spark on the oscillation frequency and deduced a general formula for it. He has also done important work in radiotelegraphy. The professor of natural philosophy (theoretical physics), Záviška, has studied the theory of electromagnetic waves, especially their flexion on parallel ring-cylinders.

INORGANIC CHEMISTRY.—The war was very unfavourable to chemical investigations: coal was sent to Germany and we were freezing in our laboratories and lecture rooms. There was no gas-supply during the daytime, platinum, accumulators, copper apparatus, etc., were confiscated by the late Austrian

Government, and no foreign periodicals (except German) were admitted. Inorganic chemistry had no tradition until 1877, when Brauner showed the aims of modern inorganic chemistry: chemical (and later physico-chemical) investigations of elements with regard to their position in Mendelejew's Periodic System. A series of results obtained was published in the Trans. Chem. Soc. Lond. since 1881. During the war Brauner published a revision of the atomic weight of praseodymium which yielded the number $Pr = 140{\cdot}94$ with a material separated from cerium and lanthanum for the first time by direct methods (not fractionation). The value obtained agrees exceedingly well with that obtained by Baxter and Stewart in 1915, who found $Pr = 140{\cdot}924$, but were unable to remove cerium and lanthanum entirely.

A revision of the atomic weight of tin carried out by Brauner and Křepelka, and later on by Křepelka alone, gave the value $Sn = 118{\cdot}699$, agreeing exactly with that obtained by other authors. In conjunction with Th. W. Richards, Křepelka determined the atomic weight of $Al = 26{\cdot}963$ based on the analysis of the bromide, $AlBr_3$; this revision carried out at Harvard University is being continued in Prague on the chloride, $AlCl_3$.

Scandium was prepared by Prof. Štěrba-Böhm in a state of "spectral" purity (Hönigschmid found with this material $Sc = 45{\cdot}10$).

The close analogy between boric and aluminic acid has been shown by Dr. J. Heyrovský, who made a physico-chemical examination of solutions obtained by dissolving (amalgamated) aluminium in aqueous solutions of the hydroxides of the alkalies, alkaline earths, and of ammonium. He ascertained that the process in all cases is additive, consisting in the formation of a complex anion $Al(OH)_4{}^1$, provided that the cation is strongly positive. He also determined the basicity and acidity of aluminium hydroxide and its bearing on the electrolytic potential of aluminium. Aluminium must be regarded as the true "Ekaboron"; in the constitution of the above compounds, apparently pentavalent, it is really positively trivalent aluminium (4 + and 1 − = 3 +), as was explained by Brauner in his preface to a text-book of analytical chemistry.

ORGANIC CHEMISTRY.—Prof. Votoček, of the Bohemian Polytechnic High School, is continuing his well-known work on sugars and has analysed with Burda the sugar components of lichens.

ANALYTICAL CHEMISTRY.—Prof. Štěrba-Böhm and Vostřebal worked out an exact method for the quantitative determination of molybdenum as trisulphide, using an admixture of formic acid on account of its high dielectric constant.

For the analysis of minerals the result of Štěrba-Böhm and Rosický's investigation of the new mineral "ultrabasite," from Freiburg in Saxony, is important; "basic" sulphides of silver and lead preponderate over the "acid" sulphides of tin and germanium. It contains 2·2 per cent. of germanium; thus ultrabasite becomes the fourth known germanium-containing mineral.

ZOOLOGY.—Our most prominent investigator in this branch of science is Prof. František Vejdovský, of the Bohemian University, who finished during the war his life-work, "The Structure and Development of the Living Substance" (in English). This work contains many coloured drawings (illustrations), but owing to the want of the necessary means the author was hitherto unable to publish it.

Vejdovský's successor, Prof. Mrázek, is very active in the zoological investigation of Bohemia with special regard to the ecology of the lower animals in ponds and lakes.

SYSTEMATIC BOTANY.—Prof. Josef Velenovský, the chief of our school of systematic botany, who is well known for his leading work "Flora Bulgarica," has just published another great work, "Bohemian Mushrooms," 4 vols. 920 pp., Prague, 1920–1922, which is richly illustrated. In order to study all kinds of fungi growing in Bohemia, he lived for a series of summers in the chief big forests of our country. He finds, *inter alia*, that far more mushrooms are edible than is generally accepted, but there are some which are poisonous or edible according to the weather and season. From his institute a series of papers was published by Domin, Kavina, Schuster, Daněk, containing interesting morphologic, cytologic, etiologic, and phytogeographic studies.

Prof. Domin, also of Bohemian University, continues his plant geographical investigations, especially with regard to Australian plants and also the Alpine flora of the Tatra Mountains.

PLANT-PHYSIOLOGY.—In this department excellent modern work has been done by Prof. Bohumil Němec, who has published two recent text-books: "Introduction into General Biology" and "Plant-anatomy and Plant-physiology." He has also published a series of papers on the Cecidia of the Eriophylages, on the infection of root-tubercles of Ornithopus, and on the influence of centrifugal force on plant cells. It is known that he was the first to explain geotropism. It should be mentioned that from his school O. Vodrážka proved the presence of a special statolithic starch in the blossoms and sheaths of positively geotropic plants with nyclinastic motions. J. Peklo isolated a symbiotic bacteria (azobacter) from the mycetocytus of the plant-louse *Schizoneura lanigera*. The work of Vl. Ulehla on the analysis of lateral and negative geotropism of Pharbitis and its *rôle* in the climbing character, and also that on heredity of A. Brožek, who succeeded in obtaining a mosaic bastard from two pure lines of Monulus, and studied the case of a simple Mendelian heredity in blossom-patterns, should also be mentioned. E. Senft has described the *rôle* of slime-trichoms in germination. The object of other work in this institute is the physico-chemical investigation of plant-life and also its connection with the chemistry of colloids.

GEOLOGY, PETROGRAPHY, AND MINERALOGY.—These three have the best traditions of all sciences in Bohemia, for they were cultivated by the most prominent men of science since about 1800. The conditions of publication during the war and after permit only of printing special papers of a very limited extent in the Transactions of the Bohemian Academy or of reviewing articles in journals with a broader programme.

Of the geological formations in the Bohemian countries the best known are those which Barrande united under the title "Système silurien," making them classical territory in his gigantic palæontological work, "S. S. du Centre de la Bohême." To-day, putting those formations together under the designation "Barrandien," on account of a tectonic common to them, we distinguish them into a succession from the Algonkian to the Devonian.

The research of Barrandien hitherto done was principally palæontological; for the solution of stratigraphic and tectonic questions a petrographic knowledge of eruptive and sedimentary rocks and the conditions of their origin was wanting. During the last few years this work has been organised and carried out by Dr. František Slavík, professor of mineralogy and petrography in our University, with

his collaborators, for the lower horizons from the Algonkian to the Ordovician in their whole extent. Slavík and Prof. Kettner completed in a series of publications the older research of Slavík on the Algonkian; Kettner worked up in monographs the lowest Cambrian (layers of Žitec) and the lower siluric horizon of Krušná Hora from the point of view of the genesis of the sediments; Dr. Slavík, with Mrs. Dr. Slavík, has described the oolitic chamoisite ores, their sedimentary genesis and the circulation of phosphorus.

Numerous other papers on the Barrandien by Kettner, Kodym, Purkyně, now director of our State Geological Institute, and Prof. Woldřich, give detailed tectonic pictures of the single districts; Kettner and Kodym have proposed a change of Barrande's designation of the horizons which is in agreement with the recent results of their investigation.

Another formation which is extended over large areas in Bohemia and Moravia and richly divided is the Cretaceous formation. The detailed stratigraphy and facial change of this formation has been for more than thirty years the object of thorough studies by Čeněk Zahálka, who has published great monographs of the Cretaceous formation in Podřipsko, Středohoří and Eastern Bohemia, whereas the environments of Prague were in this direction investigated by his son, Břetislav Zahálka; special studies were made by Woldřich.

As regards the petrography and geology of plutonic eruptive rocks and crystalline schists, two territories were intensively studied within recent times: the Bohemian Forest and the granitic massive of Middle Bohemia.

The work of Sokol on the Bohemian Forest has yielded a basis for broader studies of the primary inhomogeneity of the magma.

The ore deposits were also intensely investigated, especially the gold-veins and beds of iron ores (Mrs. Dr. and Prof. Slavík, Kettner, Stočes).

In special mineralogy a series of crystallographic papers was published (Ježek on Johannite, Ondřej on the Bohemian quartzes, Rosický on the topaz and gypsum, Slavík on the lacroisite), and chemical papers (Šplíchal on the products of decomposition of the felspars, Rosický and Štěrba-Böhm on the ultrabasite).

GEOGRAPHY.—During the war this science centred round the "Bohemian Geographical Society," which, in spite of the difficult conditions, was able to issue its transactions in the "Sborník." Owing to the Austrian censorship political geography was very limited and chiefly physical geography was cultivated. The fall of Austria means, of course, a new era for our political geography. Prof. Daneš's studies on the population of the industrial districts of Bohemia and Prof. Dvorský's on Yugoslavia as well as his book, with a political programme, on the territory of the Czechoslovak people, are the prominent works in this branch. A great work was started in ethnography with the first volume of the "Ethnography of the Czechoslovak People" (editor K. Chotek).

The chief geomorphological works based on geology and tectonics are: Prof. Daneš's on the "Kras" (Kars) of Australia and Java, Absolon's on the Moravian "Kras" (Kars), Dědina's on north-eastern and Sokol's on western Bohemia, and Vitásek's on the upper Odra district. An interesting monograph on Czechoslovak earthquakes has been written by Koláček. The military geographical State Institute, founded at the beginning of the Republic, published a series of fine maps of our new state, both charts of large areas as well as special maps, 1 : 25,000 and 1 : 75,000.

Wheat Prices and Rainfall in Western Europe.

IN an article on "Weather and Harvest Cycles" in the *Economic Journal* of December last Sir William Beveridge gave index-numbers showing the fluctuation of wheat prices in each year from 1500 to 1869, and made a preliminary mathematical and arithmetical analysis of these figures with a view of discovering periodicity in the yield of harvests, which might be attributed to periodicity in the weather. In a paper read to the Royal Statistical Society on April 25, he has now given the results of a much fuller analysis, involving a test of the same figures by harmonic analysis, for the discovery of practically all possible periods between 2 and 84 years' length. The following is a summary of the paper.

The amplitudes for more than 300 trial periods altogether have been calculated for a sequence of about 300 years from 1545 onwards, while for a number of these trial periods amplitudes have been calculated separately for the first 150 years and for the second 150 as well. These are shown on a periodogram from $q=150$ (2 years) to $q=3\cdot6$ (84 years). Each of the apparent periods indicated by the periodogram is considered in the light of four tests of periodicity: namely, the test of intensity (that is to say, comparison of the actual amplitude with the expectancy); the test of changing signs (both the elements a and b being required by theory to change signs in the neighbourhood of a period); the test of continuity (that is to say, indicating the same period, with agreement of phase as well as length, in each half of the sequence); and the test of agreement with other records (that is to say, the discovery of a similar periodicity in rainfall, temperature, or some other meteorological element). Particular importance is attached to the third of these—the test of continuity.

The results of this analysis are summarised in a table showing some 20 apparent periods ranging in length from 2·2 to 68 years. These are arranged in four groups:—

(1) Periods the reality and persistence of which is beyond doubt, strong evidence from the analysis of wheat prices being confirmed by close agreement of first-rate meteorological evidence. This group includes the period of 2·200 years discovered originally by Mr. C. E. P. Brooks, and later by Mr. J. Baxendell in rainfall; the period of 5·1 years discovered by Mr. J. Baxendell in wind and rainfall and by Capt. D. Brunt in Greenwich temperature; and the period of about 35 years discovered in 1890 by Dr. Brückner in temperature, rainfall, and barometric pressure.

(2) Periods strongly indicated by the wheat prices but for which meteorological confirmation is, at present, weaker or lacking. This group includes seven periods of 5·671, 9·750, 12·840, 15·225, 19·900, 54·000 and 68·000 years. Most of these periods are relatively long, a fact which helps in explaining failure

to demonstrate them hitherto in meteorological records. For most of them some meteorological parallel can in fact be found.

(3) Periods for which there is good, but not first-rate, evidence both in wheat prices and in meteorology. There are four of these with lengths of 3·415 years, 4·415 years (traced by Mr. Baxendell in rainfall), 5·960 years (traced by various writers in barometric pressure), and 8·050 years (no doubt the same as the period to which Prof. H. L. Moore and others have directed attention).

(4) The fourth group includes periods, some of which no doubt have reality, but all of which present inconstancy of action, changes of phase or other puzzling features. These include periods of 2·735, 5·423, 7·417, 12·050 and 17·400 years in addition to the well-known eleven-year period of the sunspots, which reappears in wheat prices with much of its normal instability of character.

The large number of periods found is striking. On *a priori* grounds, however, there is nothing really surprising in the suggestion of so many separate periodicities in the weather. Comparison between the weather cycles indicated by analysis of wheat prices from 1550 to 1850 and the actual rainfall in the ensuing 72 years, 1850 to 1921, confirms the view that these periodicities are real and important. For the purpose of this comparison, 11 of the 13 cycles in the first three groups are combined by a simple graphic method, the lengths and phases taken being exactly those determined by harmonic analysis; the combined result is shown in a single "synthetic curve" and is compared with the rainfall at 24 stations in Western and Central Europe (*i.e.* roughly the same area as that covered by the wheat prices records). A very high measure of agreement appears between the synthetic curve derived from wheat prices before 1850 and the rainfall as actually recorded after 1850.

In particular, the synthetic curve shows depressions foretelling lack of rain (which, in the area under review, is generally beneficial to wheat) at each of the markedly dry years in the past 70, namely 1857, 1864, 1870, 1874, 1883–4, 1887, 1898, 1904, 1908–9, 1921. It shows peaks foretelling heavy rain in the rainy years 1852, 1866, 1872, 1876 (for 1877), 1906, 1912, 1916. The only important discrepancies are the failure of the synthetic curve to show peaks for the rainy years, 1860 and 1903, and a depression for the somewhat local, though severe, drought of 1893. In other words, the synthetic curve which, subject to certain reservations, could have been drawn in 1850, if then drawn, would have foretold nearly all the important droughts and rainy seasons of the next 70 years. The drought of 1921 stands out quite remarkably well.

In view of the inevitable errors in the simple hypothesis upon which the synthetic curve has been constructed, the very large measure of agreement obtained in spite of these errors is all the more convincing as to the substantial correctness of the results of the analysis. The question whether definite periodicities in the weather exist and can be discovered, must now be answered in the affirmative.

The two most interesting questions of all must still be left unanswered. The first is, what will be the weather next year and in the following years. As to that no prophecy is made at all; rather, the opportunity is taken of definitely withdrawing anything which might have appeared like a prophecy in the earlier paper. The author is not prepared to say anything as to whether 1923 will be wet or dry. The full mathematical analysis in many ways has confirmed the earlier conclusions, but in more important ways goes beyond them; the general result might be quite different. Trustworthy prophecy of general weather conditions on the basis of periodicities now demonstrated should become possible in the near future, but only after a far more elaborate investigation than it has yet been possible to make.

The second question is, as to the seat and the physical cause of the periods appearing in the weather. A further analysis of the economic data may be helpful in some directions, but for the most part, that is a question for astronomers and physicists and should be left for them to answer.

The Teaching of Natural History in Schools.[1]

PROF. HICKSON and the other distinguished zoologists who have drafted the memorandum referred to below are deeply and properly concerned at the general neglect of zoology as a school subject. They maintain that this science should serve as a means of introducing youth to many of the greatest problems of life, and they therefore express astonishment, which will be shared by many people, at the findings of the investigators of the Secondary School Examinaton Council on the subject of school natural history. This body, in a recently issued report, committed itself to the remarks that "very few of the candidates (for certain important school examinations) offer this subject (Natural History), and it seems very doubtful whether it is worth while to maintain it as qualifying for a Pass with Credit in Science."

The members proceeded to express the opinion that the principles of biological science can be better illustrated by means of botany. From this latter view the authors of the memorandum dissent vigorously, and although the arguments they use will not perhaps appeal to botanists, there can, we think, be no doubt that all fair-minded botanists will support their conclusion that the principles of biology cannot be taught without reference to the animal kingdom.

More is wanted, however, than vigorous protest against examiners' opinions. Zoology is a science of vast range and school time is already taken up with many subjects. It devolves on the teachers of zoology to show in detail the kind of zoological syllabus that can be put into operation in schools as a basis for zoological teaching. In the drafting of such a syllabus they would naturally consult those teachers who have succeeded in maintaining and popularising zoology in their schools. As a preliminary to such a useful piece of work it would be necessary for zoologists to make up their minds whether it would be better to give the school zoology mainly or exclusively a natural history bias, or to attempt to treat the subject experimentally. There are arguments in favour of either method, and it might be found possible to draft alternative courses. With carefully drawn detailed syllabuses to guide instructors, and with occasional University courses for teachers, it should not prove impossible to secure for natural history a place in the curriculum of every school.

F. K.

[1] "Memorandum on the Teaching of Natural History in Schools," prepared by the Zoology Organisation Committee at the request of the Committee of Section D, British Association, Edinburgh, 1921.

A Modified Octet Theory.

IN an interesting paper on electronic structures in unsaturated molecules, published in the Journal of the American Chemical Society for March, Mr. E. D. Eastman discusses multiple bonds in relation to the octet theory of atomic structure due to G. N. Lewis. It is assumed that the pair of electrons possessed by elements of the first period (except hydrogen), although usually not acting as valency electrons, and forming a shell persisting throughout the entire period of elements, may take part in the formation of outer groups of octets when it is otherwise difficult for these to be formed. The double bond is then pictured as one atom in which the central electrons have been drawn into the outer octet, joined by two electrons to another atom in which the normal arrangement is preserved. In cases of triple bonding the two inner electrons are assumed to have been drawn into the outer shell of two adjacent atoms, there being again two electrons held in common.

The arrangements are illustrated by the formulæ of ethane, ethylene, and acetylene, in which the symbols indicate nuclei and all outer electrons are shown as dots:—

$$\begin{array}{c} \mathrm{H}\ \ \mathrm{H} \\ \mathrm{H}:\cdot\ddot{\underset{\cdot\cdot}{\mathrm{C}}}\cdot:\cdot\ddot{\underset{\cdot\cdot}{\mathrm{C}}}\cdot:\mathrm{H} \\ \mathrm{H}\ \ \mathrm{H} \end{array} \qquad \begin{array}{c} \mathrm{H}\ \ \mathrm{H} \\ :\cdot\ddot{\underset{\cdot\cdot}{\mathrm{C}}}\cdot:\ddot{\underset{\cdot\cdot}{\mathrm{C}}}: \\ \mathrm{H}\ \ \mathrm{H} \end{array} \qquad \mathrm{H}:\ddot{\underset{\cdot\cdot}{\mathrm{C}}}:\ddot{\underset{\cdot\cdot}{\mathrm{C}}}:\mathrm{H}$$

Ethane. Ethylene. Acetylene.

Multiple bonds are apparently formed only by elements of the first period.

To meet the requirements of facts relating to stability, reactivity, and free rotation, the electrons of unsaturated octets are assumed to be held in equilibrium positions at greater distances from the nucleus than in the ordinary case, the transfer from the extended position to the usual ones liberating energy. No attractive force between electrons is assumed, and the electronic arrangement is taken as cubic, though subject to distortion. The structure of carbon dioxide is probably unsymmetrical, rather than the arrangement of three nuclei in line commonly assumed. The structures of the nitrogen and oxygen molecules are represented by the following symbols:—

$$:\ddot{\underset{\cdot\cdot}{\mathrm{N}}}:\ddot{\underset{\cdot\cdot}{\mathrm{N}}}: \quad \text{and} \quad :\cdot\ddot{\underset{\cdot\cdot}{\mathrm{O}}}\cdot:\ddot{\underset{\cdot\cdot}{\mathrm{O}}}:$$

Many chemical facts discussed in the paper should prove of interest to chemists, who cannot ignore the undoubted difficulties introduced by multiple bonds in the present theory of molecular structure.

University and Educational Intelligence.

BRISTOL.—The Vincent Stuckey-Lean scholarship in botany, tenable for one year and value 36*l.* with free access to the department of botany, is offered. Further information may be obtained from the Registrar, the University, Bristol. Applications for the scholarship must be received not later than Saturday, May 20.

LONDON.—The following lectures, which will be open to the public free and without ticket, have been arranged:—At King's College, a course of three lectures on Tertiary Igneous Action in Britain, by Dr. Alfred Harker, on May 17 and 31 at 5 o'clock, and on May 24 at 4 o'clock, a course of four lectures on The Development of the Head Muscles of Vertebrates, by Prof. F. H. Edgeworth, at 5.30 P.M., on May 22-25, and one lecture by Prof. J. F. Van Bemmelen, of the University of Groningen, on The Morphological Character of the Skin Pattern in Insects and Mammals, on May 17 at 5.30 P.M. At Birkbeck College, a course of three lectures on Recent Work with regard to the Influence of Soil Conditions on Agriculture, by Dr. E. J. Russell, on Fridays, commencing May 12 at 6 o'clock, and one lecture on Whorled Phyllotaxis, by Prof. J. C. Schoute of the University of Groningen, on May 11 at 5.30 P.M. At the School of Oriental Studies, a course of three lectures on The Idea of Personality in Sufism, by Dr. R. A. Nicholson, on Wednesdays, commencing May 17 at 5 o'clock. At the London School of Economics two lectures on Modern Views of Indo-European Origin, by Dr. Peter Giles, on Fridays, commencing May 12 at 5 o'clock.

THE following advanced lectures in medicine will be given in French at the Rooms of the Royal Society of Medicine, 1 Wimpole Street, W 1, at 5 P.M.: on May 22, "Anti-anaphylaxie," by Prof. F. Widal; on May 25, "De l'Érythrémie, (Maladie de Vaquez-Osler)," by Prof. H. Vaquez; and on May 31, "Des reflèxes de défense," by Prof. J. Babinski.

MR. W. H. REED, a former mayor of the city of Exeter, has purchased and presented to the Governors of the University College, Exeter, the mansion house of Streatham Hall and part of the Streatham Hall estate, to be used as the site of the University College of the South-west of England. The Governors have purchased the adjoining farm and lands so that the new College will enter into possession of a site of 120 acres. It is expected that the incorporation of the new University College, the establishment of which has been approved by the University Grants Committee, will be effected this summer. Streatham Hall is placed on rising ground to the north-west of the city. It is near the stations and conveniently situated in every respect. The estate is admirably laid out and commands a prospect over the Exe valley to Dartmoor. It is intended to place on the new site not only the College buildings but also the hostels and playing fields.

A CONFERENCE of representatives of universities of Great Britain and Ireland will (as we announced last week) be held at University College, London, on Saturday, May 13. The holding of such annual conference was resolved upon at the First Congress of the Universities of the British Empire, but, owing to the war, the realisation of this project was postponed although conferences for special purposes were held in the years 1917–1920. At the Second Congress of Universities of the Empire in 1921 the resolution in favour of annual conferences was re-affirmed and it was decided that the month of May would be a convenient time for holding them. All the home universities were invited to suggest agenda and from these suggestions the Standing Committee of Vice-Chancellors selected the subjects which appeared to be most suitable for discussion at the present time, namely, the urgent need for the provision of enlarged opportunities for advanced study and research in British universities, the increase of residential accommodation for students, specialisation in certain subjects by certain universities, and organisation of adult education as an integral part of the work of the universities.

THE Report of its Principal Officer on the work of the University of London during 1921–22 gives the following among other statistics for the three years 1913–14, 1920–21, 1921–22: total admissions of students, 3852, 6728, 7092; candidates for examinations (final) for degrees—1807, 1746, 2455 (external candidates only—907, 710, 912); names on the roll of internal students on May 1, 4888, 7870, 8758.

Hostel accommodation for students at King's College is being substantially increased, a grant of 12,000*l.* having been allocated to this purpose. Among noteworthy events of the year were the following: the opening of the Unit of Obstetrics and Gynæcology at the Royal Free Hospital for Women and of the Institute of Historical Research; the inauguration of professorships of history, central European history, history and culture of British Dominions in Asia, sanskrit, physics, and five medical school professorships; the institution of a Bachelorship in dental surgery and of a B.A. degree and diploma in Slavonic studies; the creation of a staff tutorship for University Extension Tutorial Classes; and the formation of a Union Society on the lines of those of Oxford and Cambridge. The report foreshadows the establishment, in close association with the University, of a central Post-graduate Medical School and Institute of State Medicine, a site for the purpose adjoining the University's Bloomsbury estate having been acquired by the Rockefeller Foundation which recently offered to provide 2,000,000 dollars for the furtherance of these objects. Arrangements were made during the year with the University of Paris for six members of the Faculty of Medicine to lecture in London, and six similar exchanges in various departments of science were arranged with four Dutch Universities. The report closes with an eloquent and stimulating reminder of present-day university educational aims.

THE council of the British Medical Association announces that an Ernest Hart Memorial Scholarship, tenable for one year, of the value of 200*l.*, for the study of State medicine, and three Research Scholarships, each of the value of 150*l.*, and tenable for one year, for the investigation of a subject relating to the causation, prevention or treatment of disease, are to be awarded. Grants in aid of research in these subjects will also be made. Preference will be given to members of the medical profession and to applicants who propose to undertake to investigate problems of practical medicine. Applications for scholarships and grants should reach the Medical Secretary of the Association, 429 Strand, W.C.2, not later than June 24 next.

THE Board of Education has just published a table of holiday courses which will be held in England and Wales during the coming summer (H.M.S.O. 6d). In addition to general courses for teachers at most of the centres, there are special courses in the following subjects:—biology, at Aberystwyth and Saltburn; practical geography, at Nottingham, Scarborough, Falmouth, Brecon, Barry, Bangor, Oxford, and Bristol; economic geology, at Camborne; mine surveying, at Camborne, Amman Valley, Cardiff, and Penarth; mechanical, electrical, and civil engineering, at Cardiff and Penarth; psychology, at Brighton, Derby, Nottingham, Repton Hall, and Bangor; science courses for teachers, at Cardiff, Barry, Penarth, Oxford, Weston-super-Mare, and Repton Hall; sociology, at Edinburgh; oceanography and fisheries, at Barrow-in-Furness; botany, chemistry, mycology, and entomology applied to everyday life, at Wye; and climatology and the relations between geological structure and agriculture, at Midhurst, the country hostel of the London School of Economics. In this course, Prof. W. T. Gordon and Dr. E. J. Russell will lecture; of the other courses, about half are being organised by various educational bodies and the remainder by local education authorities and neighbouring universities. The table gives the dates of each course, the fees, the principal subjects of instruction, the address of the local secretary, and other particulars.

Calendar of Industrial Pioneers.

May 11, 1830. Friedrich Albrecht Winsor died.—A native of Brunswick, Winsor settled in England about the end of the eighteenth century. He lectured upon the use of gas, in 1806 had an exhibition of appliances at 97 Pall Mall, London, and early the following year lit a part of that street with gas. This was the first street lighted in that way. He was connected with the Westminster Gas Light and Coke Company, and in 1815 went to Paris, where he died; there is a cenotaph to his memory in Kensal Green Cemetery.

May 13, 1883. James Young died.—The originator of the paraffin industry, Young was born in Glasgow in 1811, became an assistant to Thomas Graham, the chemist, and was then successively manager to Muspratt and to Tennant. Through a suggestion of Lyon Playfair, Young was led to the investigation of a petroleum spring at Alfreton, Derbyshire, and in 1850 took out a patent for the dry distillation of coal. Entering into partnership with Meldrum and Binney, he founded works in Scotland, where naphtha, lubricating oils, paraffin for burning and solid paraffin were produced.

May 13, 1884. Cyrus Hall M'Cormick died.—The son of an American farmer who had introduced various labour-saving appliances, M'Cormick began work on the reaping machine in 1831, three years later took out a patent, and in 1847 started a factory for manufacturing his machines in Chicago. It was afterwards said that owing to M'Cormick's invention "the line of civilisation moves westward thirty miles each year." Many honours fell to him, and he was made a corresponding member of the Paris Academy of Sciences as having done more for the cause of civilisation than any other living man.

May 14, 1852. Walter Hancock died.—A member of the family whose name is associated with the rise of the British rubber industry, Hancock was born in Wiltshire in 1799. Between 1824 and 1836 he made a large number of experiments with steam road carriages, in 1832 built the *Era* which ran between London and Brighton, and the following year constructed the *Enterprise* which ran between Paddington and the City.

May 14, 1915. John Samuel White died.—The founder of a well-known firm of shipbuilders and engineers at East Cowes, White was one of the pioneers of the fast steamboat for naval purposes. To increase the manœuvring power of his boats he brought out the double rudder system with the deadwood removed.

May 15, 1888. Charles François Hervé Mangon died.—A student of the École Polytechnique and the École des Ponts et Chaussées, Mangon, though originally employed on railway engineering, was best known for his works on irrigation and drainage and the application of science to agriculture. He held a chair in the École des Ponts et Chaussées, was a member of the Paris Academy of Sciences, and for a time was director of the Conservatoire des Arts et Métiers.

May 17, 1910. Philip Cardew died.—From the Military Academy at Woolwich Cardew passed into the Royal Engineers and afterwards specialised in the application of electricity to purposes of war. He was instructor in this subject at Chatham and became known for his inventions, among which were the hot-wire voltmeter and the vibrating transmitter for telegraphy. In 1888 he became the first electrical adviser to the Board of Trade. E. C. S.

Societies and Academies.

PARIS.

Academy of Sciences, April 10.—M. Emile Bertin in the chair.—E. **Borel**: Arithmetical definition of a distribution of masses extending to infinity and quasi-periodic, with average density zero.—I. **Fredholm**: An application of the theory of integral equations.—J. **Andrade**: The mechanical problems of regulating springs.—P. **Vuillemin**: A new species of Syncephalastrum: the affinities of this genus.—E. **Vessiot**: The conformal geometry of systems of circles.—M. **Janet**: The invariant canonical forms of algebraical and differential systems.—T. **Carleman**: Demonstration of a theorem of M. Borel.—A. **Myller**: Remarks on M. Carleman's note.—A. **Myller**: Some properties of ruled surfaces in connection with the theory of parallelism of M. Levi-Cività.—H. **Chrétien** and P. **Ditisheim**: An electrochronograph recording the time, in figures, to hundredths of a second.—M. **Sauger**: A remarkable coincidence in the theory of relativity.—MM. **Berloty** and **Combier**: The eclipse of the sun of March 28, 1922, observed at the Observatory of Ksara (Syria).—I. **Tarazona**: Observation of the annular eclipse of the sun of March 27-28, 1922, made at the astronomical Observatory of Valencia (Spain).—J. **Guillaume**: Observations of the sun made at the Lyons Observatory during the fourth quarter of 1921. Observations were possible on 76 days during the quarter. The results are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—H. **Chaumat**: An arrangement permitting the elimination and determination of the correction factor of wattmeters.—C. **Dévé**: The noise caused by aeroplanes. The pitch of the sound heard as an aeroplane is passing overhead varies according to the distance of the observer's ear from the ground, rising about two octaves when the ear is lowered to about eight inches from the soil. Possible causes of this phenomenon are discussed.—J. **Galibourg** and F. **Ryziger**: A method of recognising cultivated Japanese pearls. The hole usually drilled in the pearl for attaching to an ornament is utilised. A mirror is formed by placing a minute drop of mercury in this hole, the pearl is illuminated from the side and the structure examined microscopically. Differences between the natural and cultivated pearl are brought out in this way, and reproductions of photographs illustrating the differences observed are given.—P. M. **Monval**: The preparation of ammonium chloride. Determinations of the solubilities in saturated solution of sodium chloride, sodium carbonate, ammonium chloride, and ammonium carbonate, singly and in combination, the results being summarised on a Le Chatelier square diagram.—P. **Riou**: The velocity of absorption of carbon dioxide by alkaline solutions. A contribution to the experimental study of the ammonia-soda process.—C. **Chéneveau**: An application of the optical method of determination of the solubility of one liquid in another.—R. **Fosse** and A. **Hieulle**: The tendency of formaldehyde to form hydrocyanic acid by oxidation in an ammoniacal silver solution. Formaldehyde was oxidised in strongly ammoniacal solutions containing ammonium chloride and silver nitrate by a large excess of potassium permanganate. Working with 10 milligrams of formaldehyde in each experiment, a yield of 30-36 per cent. of hydrocyanic acid was obtained.—A. **Lanquine**: The direction and dislocations of the Cheiron strata to the south of the upper Estéron, up to the high valley of Loup (Maritime Alps).—A. **Guébbard**: Remarks on the last Provençal earthquake.—P. **Garrigou-Lagrange**: Great movements of the atmosphere and weather prediction.—E. **Gain**: The ultra-maximum temperature supported by the embryos of *Helianthus annuus*. If the seeds are gradually dried and heated by stages, with interposed periods of cooling, the seed can survive exposure to much higher temperatures than has been hitherto supposed. One lot of seeds submitted to this treatment gave 80 per cent. germination after a final exposure to 145° C., but this result was exceptional; another lot of seeds gave only 2-5 per cent. of germinations after the same exposure.—A. **Petit**: Concerning the "awakening" of arable earth. In a recent paper A. Lumière has pointed out the favourable effect on soil of a thorough washing with water. This washing acts as though it removed products opposed to the germination of seeds. The author directs attention to the fact that he published similar observations in 1909.—W. **Kopaczewski**: The differentiation of phenomena of shock by contact.—R. **Bayeux**: Maximum respiration at very high altitudes. An account of experiments on two subjects at Chamonix (1050 metres), the Vallot Observatory on Mont Blanc (4370 metres), and at intermediate heights.—W. **Koskowski**: Nicotine and the inhibitory nerves of the heart. Nicotine does not act on the heart by the intermediary of the pneumogastric nerve, but directly on the intracardiac ganglia.—J. **Mawas**: The lymphoid tissue of the spiral valve of the middle intestine of *Ammocœtes branchialis* and its morphological significance.—A. **Dehorne**: The muscular histolysis and phagocytosis in the cœlom of the Nereids at sexual maturity.—K. **Abrest**: The toxic index of illuminating apparatus, of heating apparatus, and of explosion motors. The ratio of carbon monoxide to carbon dioxide produced in any form of lighting or heating apparatus is termed the toxic index. This magnitude has been estimated for various forms of lighting burners and radiators, and in the exhaust of explosion motors.

Academy of Sciences, April 18.—M. Emile Bertin in the chair.—E. **Goursat**: The problem of the thrust of earth. It is shown that the partial differential equations of M. Boussinesq, modified by M. Remoundos, can be reduced to an integrable form.—E. **Borel**: Physical hypotheses and geometrical hypotheses.—E. **Ariès**: The maximum of the latent heat of evaporation.—G. **Valiron**: Integral functions.—E. **Belot**: The *rôle* of nebular media in the dynamics of stellar and planetary systems.—L. **Bull**: An apparatus for the rapid dissociation of images in kinematography by the electric spark. The film is stationary and the images, illuminated by electric sparks (at the rate of 50,000 per second), are received on a rotating total-reflection prism. The one disadvantage of the method is that the images are not parallel to each other from one end of the film to the other.—A. **Nodon**: The photogenic action of ultra-radiations.—E. **Darmois**: The action of acids on ammonium molybdo-malate. The polarimeter shows that this ammonium salt is very sensitive to the action of acids, and the diminution of the rotation appears to be proportional to the concentration of the hydrogen ions. The use of this method readily detects traces of sulphuric acid in vinegar.—A. **Braly**: A new method for the detection of gold and silver in minerals by means of the blowpipe.—A. **Schoep**: Soddite, a new radioactive mineral. This is a yellow crystalline mineral found associated with curite from Kasolo (Belgian Congo). It is a uranium silicate of the composition $12UO_3 . 5SiO_2 . 14H_2O$, and its radioactivity is in proportion to its high uranium content (86 per cent. UO_3). The name

soddite is proposed for the mineral.—J. **Thoulet**: Deep submarine volcanic eruptions. Evidence of submarine eruptions furnished by deep-sea soundings near the Canaries and the Azores.—R. **Souèges**: The embryogeny of the Rosaceæ. The first stages of the development of the embryo in *Geum urbanum*.—M. and Mme. F. **Moreau**: Mycelium with protuberances found in the Ascomycetes.—J. **Stoklasa**: The influence of selenium and of radium on the germination of seeds. Both sodium selenate and selenite exert a toxic action on the development of seeds, the latter possessing the most marked effect. This toxic effect is partially neutralised if radioactive substances are present at the same time.—R. **Argaud**: The intranucleolar presence of the centrosome.—A. **Lumière** and J. **Chevrotier**: Antityphoid vaccination by scarification. As an alternative to vaccination by the mouth, which as yet has not been fully accepted, trials have been made of a process of immunisation by scarification. This method is free from the troublesome reactions caused by direct injection, but the immunity conferred is not quite complete.—MM. **Cohendy** and E. **Wollman**: Some results obtained by the method of growth under aseptic conditions. Experimental scurvy. Infection of the aseptic guinea-pig by cholera.—L. **Corbière** and A. **Chevalier**: The origin of *Spartina Townsendi* and its *rôle* in the fixation of marine mud.

Diary of Societies.

FRIDAY, MAY 12.

ROYAL ASTRONOMICAL SOCIETY, at 5.—J. Halm: A Method of determining Photographic Star Magnitudes without the Use of Screens or Gratings.—J. Halm: The Rotation of the Sun's Reversing Layer.—J. Evershed: Widened Lines in the Spectrum of Sirius.—A. Stanley Williams: Two Variable Stars in Gemini.—A. Stanley Williams: A Probably Variable Star in Gemini.—A. Stanley Williams: The Tawny Hue of Jupiter's Equatorial Belt.—A. N. Brown: Observations of RT Cygni (Ch. 7085) in 1917–22.—W. H. Steavenson: Observations of Nova Persei (1901) in 1921–22.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—S. O. Pearson and H. St. G. Anson: Demonstration of Some Electrical Properties of Neon-filled Lamps.—Dr. A. Griffiths and W. T. Heys: A New Apparatus for the Measurement of the Polarisation Capacity of Platinum Plates in Sulphuric Acid.—Dr. H. Chatley: The Molecular Forces involved in Cohesion.

ROYAL SOCIETY OF MEDICINE (Clinical Section), at 5.30.—Annual General Meeting.

JUNIOR INSTITUTION OF ENGINEERS (at Institution of Mechanical Engineers), at 7.30.—L. A. Legros: Tanks and Chain Track Artillery.

MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society).

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Dr. H. H. Dale: The Search for Specific Remedies.

SATURDAY, MAY 13.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. O. W. Richardson: The Disappearing Gap between the X-ray and Ultra-violet Spectra. I. Grating Results.

MONDAY, MAY 15.

ROYAL GEOGRAPHICAL SOCIETY (at Lowther Lodge, Kensington Gore), at 5.—E. A. Reeves: The Evidence of a True North and South Directive Force in the Atmosphere.

ARISTOTELIAN SOCIETY (at University of London Club, 21 Gower Street, W.C.1), at 8.—Prof. T. P. Nunn, and others: Discussion on Prof. Whitehead's "Enquiry" and "Concept of Nature."

ROYAL SOCIETY OF ARTS, at 8.—F. F. Renwick: Modern Aspects of Photography (3) (Cobb Lectures).

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—J. A. Gotch: The First Half-century of the R.I.B.A.

TUESDAY, MAY 16.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. W. Bulloch: Tyndall's Biological Researches and the Foundations of Bacteriology (Tyndall Lectures) (I.).

ROYAL SOCIETY OF MEDICINE (General Meeting of Fellows), at 5.

ROYAL STATISTICAL SOCIETY, at 5.15.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—J. F. Shepherd: Natural Colour Photography.

WEDNESDAY, MAY 17.

ROYAL METEOROLOGICAL SOCIETY, at 5.—Dr. A. E. M. Geddes: Weather and the Crop-Yield in the North-East Counties of Scotland, followed by a general discussion on R. H. Hooker's Presidential Address, The Weather and the Crops in Eastern England, 1885–1921.—Dr. H. P. Waran: A New Form of Direct-reading Barometer.

ROYAL SOCIETY OF MEDICINE (Surgery Section), at 5.30.—Annual General Meeting.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Annual Exhibition of Microscopic Pond Life.

THURSDAY, MAY 18.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. F. Keeble: Plant Sensitiveness (II.), To Contact and to Chemical Stimulation.

ROYAL SOCIETY, at 4.30.—*Probable Papers*.—Prof. T. B. Wood and Dr. J. W. Capstick: The Progress of Metabolism after Food in Swine.—C. G. Lamb: The Geometry of Insect Pairing.—G. E. Briggs: Experimental Researches on Vegetable Assimilation and Respiration. XV. The Development of Photosynthetic Activity during Germination of Different Types of Seeds.—G. E. Briggs: Experimental Researches on Vegetable Assimilation and Respiration. XVI. The Characteristics of Sub-normal Photosynthetic Activity resulting from Deficiency of Nutrient Salts.—J. A. Gardner and F. W. Fox: The Origin and Destiny of Cholesterol in the Animal Organism. Part 13. The Autolysis of Liver and Spleen.

ROYAL SOCIETY OF MEDICINE (Dermatology Section), at 5.—Annual General Meeting.

INSTITUTION OF MINING AND METALLURGY (at Geological Society), at 5.30.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Sir Ernest Rutherford: Electricity and Matter (Kelvin Lecture).

INSTITUTION OF AUTOMOBILE ENGINEERS (London Graduates' Meeting), at 8.—P. H. Hardy and L. B. Harris: Electrical Equipment.

CHEMICAL SOCIETY, at 8, followed by an Informal Meeting.

FRIDAY, MAY 19.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botanical Lecture Theatre, Imperial College of Science and Technology), at 2.30.—W. Rushton: Further Contributions to the Biology of Freshwater Fishes.—Prof. J. H. Priestley: Toxic Action of Illuminating Gas on Plants (with Demonstration).

ROYAL SOCIETY OF MEDICINE (Otology Section), at 5.—Annual General Meeting.

INSTITUTION OF ELECTRICAL ENGINEERS (London Students' Section) (Annual General Meeting), at 7.—A. H. Reeves: The Elimination of Atmospherics in Radio-telegraphy.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—Sir William Bragg: The Structure of Organic Crystals.

SATURDAY, MAY 20.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—Prof. O. W. Richardson: The Disappearing Gap between the X-ray and Ultra-violet Spectra. II. Photo-electric Methods.

PUBLIC LECTURES.

(*A number in brackets indicates the number of a lecture in a series.*)

FRIDAY, MAY 12.

LONDON SCHOOL OF ECONOMICS, at 5.—Dr. P. Giles: Modern Views of Indo-European Origins (1).

UNIVERSITY COLLEGE, at 5.15.—A. E. M. van der Meersch: Simplified Solutions for B.M. and S.F. Values for Rolling Loads (1);—at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (2).

BIRKBECK COLLEGE, at 6.—Dr. E. J. Russell: Recent Work with regard to the Influence of Soil Conditions on Agriculture (1).

GRESHAM COLLEGE, at 6.—A. R. Hinks: Astronomy (4) (Gresham Lectures).

TUESDAY, MAY 16.

UNIVERSITY COLLEGE, at 5.—Sir Arthur Shipley: Insects and Disease (3).

KING'S COLLEGE, at 5.30.—Prof. H. Wildon Carr: The Principle and Method of Hegel (3): The Philosophical Sciences.

GRESHAM COLLEGE, at 6.—Sir Robert Armstrong-Jones: Physic (1) (Gresham Lectures).

WEDNESDAY, MAY 17.

SCHOOL OF ORIENTAL STUDIES, at 5.—Dr. R. A. Nicholson: The Idea of Personality in Sufism (1).

UNIVERSITY COLLEGE, at 5.15.—Dr. D. H. Scott: The Early History of the Land Flora (4).

KING'S COLLEGE, at 5.—Dr. A. Harker: Tertiary Igneous Action in Britain (1);—at 5.30.—Prof. J. F. Van Bemmelen: The Morphological Character of the Skin Pattern in Insects and Mammals.

GRESHAM COLLEGE, at 6.—Sir Robert Armstrong-Jones: Physic (2) (Gresham Lectures).

THURSDAY, MAY 18.

UNIVERSITY COLLEGE, at 2.30.—Prof. W. M. Flinders Petrie: Recent Discoveries in Egypt (1);—at 5.15.—Sir Joseph J. Thomson: Atoms, Molecules, and Chemistry (3).

ST. MARY'S HOSPITAL (Institute of Pathology and Research), at 5.—Major-Genl. Sir W. B. Leishman: Enteric Fevers in the War.

GRESHAM COLLEGE, at 6.—Sir Robert Armstrong-Jones: Physic (3) (Gresham Lectures).

FRIDAY, MAY 19.

LONDON SCHOOL OF ECONOMICS, at 5.—Dr. P. Giles: Modern Views of Indo-European Origins (2).

UNIVERSITY COLLEGE, at 5.15.—A. E. M. van der Meersch: Simplified Solutions for B.M. and S.F. Values for Rolling Loads (2);—at 5.30.—Prof. W. R. Shepherd: The Expansion of European Civilisation (3).

BIRKBECK COLLEGE, at 6.—Dr. E. J. Russell: Recent Work with regard to the Influence of Soil Conditions on Agriculture (2).

GRESHAM COLLEGE, at 6.—Sir Robert Armstrong-Jones: Physic (4) (Gresham Lectures).

Imperial Aspects of Comparative Medicine.

THE Advisory Committee on Research into Diseases in Animals was appointed in November 1920 by the Development Commission "to report on the facilities now available for the scientific study of the diseases of animals, to indicate what extension of those facilities is desirable in the immediate future in order to advance the study of disease whether in animals or man, and to advise as to the steps which should be taken to secure the aid of competent scientific workers in investigating diseases in animals." The Committee comprised Sir David Prain (Chairman), Prof. O. C. Bradley, Captain W. E. Elliot, M.P., Sir Walter Fletcher, Sir William Leishman, Sir John M'Fadyean, Prof. C. J. Martin, and Mr. F. B. Smith, C.M.G. The report which has now been issued (H.M.S.O., 1*s*. 6*d*. net) affirms that the problem of disease and of health, whether in man, animal or plant, is in reality one, and that the acquisition of the greater part of our knowledge of human and of veterinary medicine, both curative and preventive, has resulted from the use of identical scientific methods. Moreover, the vast overseas trade of the United Kingdom in live-stock gives it a vested interest in the wealth annually at hazard from preventible causes throughout the Empire.

With this broad interpretation of its terms of reference, the Committee has had to deal with essentially the same problem as that of the Colonial Office "Committee on Research in the Colonies," to the report of which reference was made in the issue of NATURE for March 23, p. 365.

Whereas the Committee of the Colonial Office looked to the Universities as training grounds for future investigators, that of the Development Commission has concentrated attention on the Veterinary Institutions and Laboratories. It found that in the United Kingdom the only independent institution devoted to the investigation of animal diseases to which the name "Research Institute" could be applied was at the Royal Veterinary College, London. The aggregate State subsidy received by the five Veterinary Colleges during the year 1920–21 for research purposes totalled only 3696*l*. This condition of affairs renders impossible the proper payment of workers or the maintenance of laboratories or of field inquiries, and is stigmatised by the Committee as a national disgrace. In its survey of the facilities available overseas the Committee was embarrassed by the limited information at its command, but after excepting the Veterinary Laboratory at Onderspepoort on account of its valuable work for the Union of South Africa, the Committee adopts the dictum of the editor of the Tropical Veterinary

Bulletin that the state of research into animal diseases in the tropics is at present lamentable.

Affirming that the facilities available in the British Empire in men, laboratory accommodation and equipment, are totally inadequate for the interests at stake, the Committee recommends the gradual creation of a cadre of research workers under an advisory organisation of scientific experts. On both scientific and political grounds it is desirable that no demarcation should be drawn between research work in the United Kingdom and that in other parts of the Empire.

The Committee is of opinion also that, should financial conditions become less stringent, assistance from State funds would be justified towards the creation of one strong Institute to serve the needs of the United Kingdom and possibly of the Empire. In such an institute, research would be made into the comparative aspects of disease as a whole, and workers in different branches of the subject—veterinary, medical, botanical—would be brought into association.

It is unfortunate that the Committee terminated its labours before the announcement of the gift to the Government by the Rockefeller Foundation of two million dollars for the creation of an Institute of Imperial Hygiene in London. It is understood that the Government has already accepted the responsibility of providing staff and maintenance of the Institute when established. Moreover, the "Shakespeare Memorial" site adjoining the area recently acquired for the University of London has been purchased.

This new development must enhance profoundly the position of London as the post-graduate centre of the Empire. It is understood that the Ministry of Health favours the integration of certain activities of various bodies like the London School of Tropical Medicine with those of the proposed Institute. In view of the enormous advantages which would ensue to the whole science of medicine from the intimate association of research workers in human and animal disease, it is to be hoped that serious efforts will be made to meet the legitimate aspirations of the veterinary profession for better facilities for research and post-graduate study in connection with the new Institute.

The General Theory of Relativity.

Space—Time—Matter. By Hermann Weyl. Translated from the German by Henry L. Brose. Pp. xi + 330. (London: Methuen and Co., Ltd., 1922.) 18*s*. net.

PROF. WEYL'S work is the standard treatise on the general theory of relativity. It is the most systematic and penetrating book on the subject; it is also by far the most difficult. The reader must not expect a helping hand over difficulties which are merely analytical; only the barest indication of intermediate steps is given in passing from one formula to another. The book is not suitable for a first introduction to the mathematical theory; but those who have already acquired some familiarity with the methods and manipulations required will find here a deeper insight and a more general view of the logical coherence of the theory than is possible in more elementary text-books. We think too that Weyl, more than other continental writers, approaches the outlook natural to an English student. The subtle distinctions between the Cambridge and the continental schools survive the revolution which has overtaken scientific thought. Even with Einstein we feel a need to anglicise his mode of thought, and this is still more necessary with some other German writers. But Weyl strikes just the right note for us; and though he is often too far ahead for us to follow, we pay him the (perhaps doubtful) compliment of claiming him as one of our own school of thought.

In some branches of applied mathematics the analytical methods have obviously no connection with the physical processes. The lunar theory is a notable instance; we cannot conceive that the processes by which the moon finds out where it ought to be are in any way analogous to those by which the computer solves the same problem. It is part of the charm of Einstein's theory that the mathematical methods correspond step by step with physical processes, so that not merely the result but also the form of the analysis is significant. The deeper our comprehension of the mathematical tool (the tensor calculus) the deeper will be our insight into the structure of the world. There are perhaps some who cherish the hope that ultimately simpler mathematical methods of treating these problems will be devised; but even if this hope were fulfilled the simplification would cost us dearly. If to our minds it seems simpler to solve the problems of Nature for her by methods other than those which she herself follows, that only accentuates our unfittedness to comprehend her processes. In Weyl's treatment the physical significance of each analytical operation is most strongly emphasised.

A distinctive feature of Weyl's work is his use of the conception of tensor-density in addition to tensor. These differ by a factor $\sqrt{g}$. In any region of the world, we can always choose a system of co-ordinates such that $\sqrt{g}=1$ everywhere; from the analytical point of view the factor is a useless complication which can be omitted without loss of generality, so that tensors and tensor-densities become equivalent. But this computational simplification plays havoc with the physical significance of the formulæ. Intensity-measures and

quantity-measures become hopelessly confused. Weyl seems to have been the first to insist on keeping these distinct. He brings a meaning into formulæ which had previously appeared to be artificial combinations. The student who has with difficulty acquired some skill in operating with tensors has to learn in addition how to manipulate tensor-densities; but the results repay the extra labour.

Einstein has amalgamated for us geometry and mechanics. He has shown that if we have given an exact specification of the geometry of a region of space and time, that specification will also determine all the mechanical properties existing in the region—gravitational field, inertia, momentum, and stress. Einstein accepted for this purpose the geometry of Riemann. In 1918 Weyl showed that Riemannian geometry contains a limitation which makes it appear inappropriate to the description of a physical continuum from which all action at a distance is excluded. He generalised the geometry and so gave to the state of the world additional degrees of freedom. Actually four additional quantities had to be fixed in this more general specification of geometry; and he identified these with the four electromagnetic potentials. In this way the whole electrodynamic scheme is associated with the mechanical scheme, both being amalgamated with the geometry of the world. There is, however, an element of speculation in Weyl's unification which does not appear in Einstein's; the mechanical and geometrical properties of the gravitational field are aspects of the same phenomena; the electrical and geometrical properties of the electromagnetic field are not shown to be the same phenomena though they are supposed to originate in the same source.

Nearly half of Weyl's book is devoted to the development on a logical basis of a system of geometry. In this part we have to be content with laying a foundation, with scarcely a hint of the well-known phenomena of relativity which will follow. Knowing Weyl's great reputation as a pure mathematician, we felt some apprehension lest he should approach the study of space as though it were a matter of pure geometry. The fear was groundless. He recognises fully that he is dealing with a physical subject; and in his geometry space is recognised at the outset as a *form of phenomena* (p. 11), not a mere continuum of *n* dimensions. Among the most novel investigations is a justification of the Pythagorean metric (the quadratic formula for the interval) by an argument involving the theory of groups. The reasoning is difficult to follow.

As the changes made in successive German editions bear witness, Prof. Weyl is still developing his ideas. We think that near the end of the present edition he has reached conclusions which were not in his mind at the beginning. Four pages from the end, after some illuminating remarks on the two modes of transferring a quantity from place to place by "persistence" and by "adjustment" respectively, he decides that actual transference by clocks and measuring-rods corresponds to *adjustment*. Whilst this conclusion seems to be undoubtedly correct, the reader has scarcely been prepared for it, and indeed the existence of anything with respect to which adjustment can be made has only been demonstrated a few pages earlier. But the beginning of the book needs reconsidering in the light of this conclusion. How are we to reconcile the two following statements?

(1) The same object, remaining what it is, could equally well have been in some other place. The correspondence between the portions of space occupied in the two positions is called congruent transference (p. 11).

(2) A measuring-rod even in a statical field does not in general undergo a congruent transference (p. 308).

These are not the exact words, but I think that they convey the sense intended. It would seem to follow that a measuring-rod at another place and time is not precisely the thing it was. But it must be remembered that the statement (1) was enunciated as an axiom, which we were expected to accept as a matter of common experience; it is no place for metaphysical subtleties, which indeed Prof. Weyl is not likely to indulge in. There is, I believe, a direct contradiction between the initial premises (1) and the final conclusion (2) which can only be removed by revising our ideas as to the status of Weyl's ultra-Riemannian geometry. In spite of its specialised character the geometry of Riemann is the geometry of space and time ("the form of phenomena"), as Einstein assumed. Weyl's generalisation does not refer to actual space and time; but it gives us the needful mode of treatment in graphical guise of those fundamental relations which underlie the world of space and time and things.

Not until the last third of the book do we enter on the general theory of relativity. Then in a hundred pages we hasten through all the main results, including the re-formulation of mechanics to which Weyl has so largely contributed. De Sitter's and Einstein's rival views of a curved world are compared, and we gather that the author is not so hostile as most continental writers to the former. In either case, by noticing that $G^2\sqrt{g}$ (not $G\sqrt{g}$) is the fundamental scalar-density of zero dimensions, he is able to show that the cosmical curvature-term appears naturally and inevitably. Much of the more advanced theory depends on the Hamiltonian method of stationary variation of a volume-invariant. This is applied in two forms—

(1) Variations arising from changes of the reference-

frame vanish on account of the invariance. Equations so derived are mathematical identities which cannot be controverted.

(2) The vanishing of the variation for *all* small changes of the parameters is a possible form for a law of nature. Equations so derived rest on a particular hypothesis which challenges criticism.

We wish that the author had kept the results of these two applications distinct. We believe that most of the ascertained laws of physics are derivable by the first application, and the second is responsible for some additional results which cannot be tested and do not appear to us particularly probable.

The translator of such a book as this has our sincere sympathy. He has done a useful work which yet falls far short of complete success. There are many passages in the original which we have turned to again and again, and only very slowly grasped their meaning; others still defeat us. It was not to be expected that the translator would penetrate the thought behind them, and he has evidently given up the attempt to make his rendering convey any possible sense. We would not recommend any one to make a profound study of this work without having the German original at hand to consult when a difficulty is encountered. There are other mistakes harder to excuse. Weyl's treatment of space turns on the two conceptions of affine and metrical geometry, and it is impossible to proceed without mastering these. But the exposition of affine geometry on p. 18 refers continually to postulates I and II, and the reader will search in vain for any postulates so indicated. In the German edition a misprint of 1 for I is comparatively harmless; but in the English edition the further substitution of 2 for II extinguishes the reader's last hope of discovering what the argument refers to. On pp. 141-2, two axioms are printed as though they were headlines of the paragraphs following. Absurd mistranslations such as "mass of the earth" for "mass of the world" on p. 296 will probably not do much harm, though they shake our confidence. All the same, there is much good work in the translation, and those who are struggling to master Weyl's indispensable treatise will welcome the partial aid which it affords. A. S. E.

New Methods of Arctic Exploration.

The Friendly Arctic: The Story of Five Years in Polar Regions. By Vilhjahmar Stefansson. Pp. xxxi+784+plates. (London: Macmillan and Co., Ltd., 1921.) 30*s.* net.

NO such original and assertive explorer of the Arctic regions as Mr. Stefansson has appeared since Dr. Nansen startled the admirals by dispensing with a line of retreat. Mr. Stefansson's views are however, far more upsetting than those of Dr. Nansen, for he denies practically every theory and many reputed facts regarding the North Polar area, and contemns almost all the long-established methods of Arctic travel.

We cannot go on to Mr. Stefansson's vindication of his own powers as a pioneer without first deprecating his contemptuous tone with regard to arm-chair geographers and their views. Those harmless drudges do their best to follow the published narratives of explorers and to reconcile the contradictions between successive travellers' reports. If they say in their compilations that the Arctic Sea in its farther recesses is devoid of life it is because explorers have told them so, and if they dwell upon the hardships and dangers of Arctic explorations it is because earlier and less expert explorers did suffer and perish in the attempt to do, amid difficulty and pain, what proves easy and pleasant to Mr. Stefansson. We gladly acknowledge that Mr. Stefansson treats Peary as a great and successful explorer, and does full justice to McClintock's marvellous sledge journeys on the Franklin search; but he would have thought so much more of them if they had seen how easy it was to "live off the country"!

In pp. 30-32 much is made of the assumed ignorance on the part of Sir John Murray that sea-ice after long exposure on the surface of a floe can yield drinkable water. It seems to us that Sir John Murray probably controverted Mr. Stefansson's statement on this point not from ignorance but merely in order to test his character, for it was a common thing with Murray to see if a young man who knew something could be shaken in his confidence as to his own knowledge by the weight of an older man's authority. If Mr. Stefansson had wavered, as we are very sure he did not, Sir John Murray would have thought the less of him. As a matter of fact, we know that Murray was greatly impressed by the young Canadian's knowledge and fitness. With this book before them we are sure that the works of oceanographers and arm-chair geographers will henceforth be purged of some errors and fortified by many new facts; but the whole load of learning left by the old heroes of the North will not, on that account, be thrown into the sea like Stefansson's despised canned goods.

In 1913 the Canadian Government took over and financed an Arctic expedition which Mr. Stefansson had been organising in co-operation with the National Geographic Society of Washington and the American Museum of Natural History. These institutions withdrew their claims and so Stefansson's third Arctic expedition was purely Canadian. A great programme was prepared for work in two divisions, a northern in a

strong whaler, the *Karluk*, under Mr. Stefansson himself with a large staff and complete oceanographical equipment; and a southern for work on the coast of the continent under Dr. Anderson, who was second in command, and provided with a smaller vessel. The southern party proceeded on the whole according to plan; but the *Karluk* forced her way into the ice north of Alaska on August 13, 1913, and remained fast, drifting westward. On September 20, when the ship was ten miles off the land Stefansson thought it right to go ashore for a few weeks' caribou hunting; but the ship had disappeared when he was ready to return, and after quite old-fashioned difficulties and hardships, including the crushing and sinking of the ship, most of the men succeeded in reaching Wrangel Island off the coast of Siberia and were ultimately saved. Mr. James Murray, the biologist, and Dr. Mackay, both of whom had been with Sir Ernest Shackleton in the Antarctic, were amongst those who perished on the ice.

Ignorant of the fate of the *Karluk*, and deprived by her loss of all the carefully prepared equipment and trained assistants, Stefansson had to decide whether he should accept failure or put to a test his long-cherished idea of living on the resources of what he had come to look on as a friendly Arctic. He chose the latter alternative, found two old friends amongst the Arctic traders, named Storkerson and Andreasen, who were willing to take risks, got together some sledges and dogs, a few instruments, and a large quantity of ammunition, and on March 22, 1914, started on a great journey over the sea-ice from Marten Point in 70° N. No one on shore expected to see him again. A support party was sent back on April 5, when fifty miles from shore, and the three men with six dogs and provisions for thirty days marched northward over the floes along the meridian of 140° W. By May 5, they had reached 74° N. in 135° W., and seals and bears kept them in food and fuel in an eastward march until they landed on Banks Land on June 25, after travelling a thousand miles, never having been hungry, cold, or tired, and the dogs in better condition than at the start.

The summer was spent hunting and exploring in the unknown interior of Banks Land; the ship appointed to bring supplies arrived, and the winter over Stefansson started again north-westward over the sea-ice, reaching almost 77° N. in 130° W. early in May 1915. From this point he travelled due east to Prince Patrick Land, skirted its north-west coast, and to the north-east of it discovered a new land (Borden Island) in 78° N. 115° W., and the summer being then so far advanced as to make travel over the sea-ice very difficult he hurried back almost 600 miles by the west coast of Melville Island to his old base in Banks Land. Thence opportunity was taken of a chance trader, whose ship Stefansson purchased as a matter of course, to pay a brief visit to the comparative civilisation of Herschel Island, but on returning to Banks Land the party made an interesting journey eastward to visit the Copper Eskimos of Victoria Island. After wintering in Banks Land, Stefansson in the spring of 1916 made a journey across Melville Island to Borden Island, thence north-eastward to 80° N., where another new land, Meighen Island, was discovered in 100° W., and on his way back he found a third new land, Longheed Island, in 77° N. 105° W. The winter quarters for 1916–17 were in Liddon Gulf, Melville Island, classic ground of the Franklin search.

Early in 1917 Mr. Stefansson was again on his way north, this time along the eastern coast of Borden Island and onwards over the sea-ice almost to 81° N. in 110° W. Here his two companions, who were new hands on this occasion, broke down from scurvy, due to their surreptitious diet of tinned foods during the previous winter, and the most promising of all these wonderful journeys had to be cut short. The return journey reads like a sheer romance, and Stefansson well says that if Stevenson had only known of facts like these he would never have had to invent the plot of "Treasure Island." The accumulating interest of chapters 59 to 63 is tremendous, and will prove to most European readers a revelation of what is possible in Arctic America. On September 13 Stefansson landed from his stranded steamer at a little harbour in Alaska, and here his luck deserted him, for after planning another trip into the Beaufort Sea he was attacked successively by typhoid fever, pneumonia, and pleurisy, and 1918 was well advanced before he could leave the hospital in Fort Yukon, that nothing but his indomitable spirit enabled him to reach. His old friend Storkerson undertook an eight months' journey over the Beaufort Sea north to 74°, then drifting on a floe to follow the currents, and he returned safely, showing that he also could live on the natural bounty of the friendly Arctic.

We have given a condensed narrative, for the book is confused by digressions which obscure the sequence of events. The digressions, however, are full of interest, telling much of the habits of caribou, musk-oxen, seals, polar bears, and Arctic foxes, and more of Mr. Stefansson's own special subject—the habits and beliefs of the Eskimo, and the prejudices as to diet of all sorts of men and dogs.

The scientific results are being worked out at Ottawa, and we can refer here only to the unique value of the soundings taken by Stefansson and Storkerson in the Beaufort Sea. These determine the position of the Continental Shelf on several lines at right angles to

the coast of America and to the western islands of the Arctic archipelago. They also point to great possibilities in the way of more detailed oceanographical work by sledge journeys in the future.

HUGH ROBERT MILL.

An Epic of Science.

The Torch-bearers. By Alfred Noyes. Pp. lx+281. (Edinburgh and London: W. Blackwood and Sons.) 7*s*. 6*d*. net.

EPIC is perhaps too large a word to apply to this beautiful book, though Mr. Noyes himself suggests it in his preface. There is, as he says, "an epic unity—a unity of purpose and endeavour"—in the story of scientific discovery, and "the great moments of science have an intense human interest and belong essentially to the creative imagination of poetry." The world of science and of poetry, therefore, both owe Mr. Noyes a great debt of gratitude for his attempt—the first of the kind—to bring them together; and, apart altogether from the high scope which he announces, every reader who submits himself fairly to the influence of his verse will be carried away by the charm of the language, the human, sometimes humorous, touches of character, and the triumphs, mixed with pathos, of the story.

We are told in the preface that this volume is the first of a trilogy, though the subjects of the two which are to follow are not revealed. This one deals with the pioneers of astronomy, and the other two might well be given, one to the discoverers of physics and chemistry, ending in the marvels of the electrons, and the other to the story of evolution, linking the record of geology with the gradual establishment of the continuity of organic structure. These we shall await with intense interest, and with full confidence that Mr. Noyes will do justice to the broad outlines of the theme and its human bearings, without too much concern as to the absolute accuracy of his account in details. Of course there are mistakes here and there; Kepler's laws are not quite accurately given. But what a *tour de force* to present them at all, approximately and attractively, in poetic form! Of course, too, there are plenty of prose-like lines, about which some of the critics in the press have made merry. But at the most they are a very small proportion of the whole, far smaller than in any of the long narrative poems of Wordsworth.

Speaking of Wordsworth, it is a little strange that Mr. Noyes does not invoke his great authority in favour of his enterprise in this trilogy. He invokes Matthew Arnold, who prophesied forty years ago that poetry would carry on the purer fire of human thought and express in new terms the eternal ideas of faith and hope which must be the constant stay of the human race. But Wordsworth, in the Preface to the second edition of the "Lyrical Ballads," came nearer still to Mr. Noyes's idea. He showed how the Poet, being in that respect the Man, *par excellence*, looked always "before and after" and held our human ideals together. He carried everywhere relationship and love, and wove into the fabric of his vision all that mankind has ever done or known or dreamt. Thus the material of science is just as fit an object of the poet's art as any upon which it is more usually employed. "If the time should ever come when what is now called science, thus familiarised to men, shall be ready to put on, as it were, a form of flesh and blood, the Poet will lend his divine spirit to aid the transfiguration, and will welcome the Being thus produced as a dear and genuine inmate of the household of man."

More than a hundred years have passed since Wordsworth made that prophecy. The volume of the poetry written, either in this country or abroad, with that inspiration is but slight. Tennyson gave us some thoughts suggested by the doctrine of evolution, Matthew Arnold some others. On the whole, Sully Prudhomme has come nearest to Wordsworth's ideal of the poet inspired by science, but it takes with him the guise of a stern, sad doctrine of resignation and fortitude under inexorable laws. It remained for Mr. Noyes to strike a new note, of triumph in the growth of the human spirit, of patient search for truth, of romantic beauty in the linking up of relationships between the heavenly bodies, which have inspired the worship and wonder of man since he first looked upwards.

The figures Mr. Noyes has chosen for the protagonists of his drama have all some points of personal interest, as well as permanent importance in the building up of science. These personal aspects he rightly stresses. Copernicus is described upon his death-bed, waiting for the issue of his long-delayed work. Kepler is the fantastic poet, visited by Sir Henry Wotton, who quotes verse for verse. The trial of Galileo—dramatically the most effective thing in the poem—is given in the form of letters from his daughter Celeste and from others, friends and foes, somewhat in the manner of Browning.

It is tempting to quote some of the most telling lines in the poem; one reviewer, at any rate, has read some of them several times already. Two extracts only shall be given, not by any means as among the most beautiful, but as conveying the dominating spirit of the whole. The Prologue raises the question, is there

not one to touch
With beauty this long battle for the light?
The blind, blood-battered kings
Move with an epic music to their thrones,
Have you no song, then, of that nobler war?
. . . for, in these wars,
Whoever wins a battle, wins for all.

And then of Copernicus. The first effect of the new theory was to dwarf the importance of man, to make him "creep like ants upon our midget ball of dust, lost in immensity." But this is not the true or final issue:

This new night was needed, that the soul
Might conquer its own kingdom and arise
To its full stature.

F. S. MARVIN.

Biochemistry.[1]

Biochemistry: A Study of the Origin, Reactions, and Equilibria of Living Matter. By Prof. Benjamin Moore. Pp. vii + 340. (London: Edward Arnold, 1921.) 21*s*. net.

AS is pointed out in the preface, this book does not claim to be a general text-book of biochemistry. Hence, it is necessary, in the first place, to indicate the nature of its contents. The first two chapters are new; they deal with "biotic energy" and with the relation of life to light. There is much of interest and of suggestive thought for workers in that field of vital phenomena discussed in these chapters. The author's views on "biotic energy" are well known. We may note that, while being an independent form of energy, this is supposed to be quantitatively convertible into the "inorganic" forms of energy and to obey the laws of energetics. This being so, it is difficult to see what is gained by the assumption, unless it implies the function of a directing agency or "entelechy." Perhaps the author has in his mind something of the kind, since he speaks of "biotic energy" as *controlling* the chemical reactions in the living cell. A mild criticism may be made in this connection of the somewhat hazy and unintelligible nature of occasional statements in the book. This is doubtless due to oversight; but if one were able to attach a more definite meaning to certain expressions, it is likely that they might prove more useful than appears at first sight.

The following six chapters deal with photo-synthesis. They are practically reprints of the author's papers in the Proceedings of the Royal Society. While these experiments are of much interest, and will repay perusal, some doubt may be expressed as to the need for repetition of experimental detail, since the original papers are accessible elsewhere. With regard to the formaldehyde theory of carbon assimilation in plants, it may be remembered that Prof. Moore's experiments did much to give reasonable ground for holding this view, which has recently been made still more acceptable by the work of Baly, Heilbronn, and Barker. The assimilation of atmospheric nitrogen by the cell of the green plant under the influence of light, however, requires more convincing evidence than has been brought forward as yet.

The remaining chapters are reprinted and re-edited from "Recent Advances in Physiology" and "Further Advances in Physiology." The reader will be glad to have these articles again made available, but it is to be regretted that the opportunity was not taken to bring them more adequately up to date by correcting statements which no longer represent what is known on the subject. It may savour too much of "asking for more" if the opinion be expressed that readers would have been grateful for some account of the views of Langmuir on adsorption and catalysis, and of those of Bancroft on the latter. The application of the modern conception of "activity coefficients" to physiological phenomena is also a matter worthy of consideration.

Prof. Moore gives much destructive criticism of the assumption of a semi-permeable membrane on the surface of cells. It may be pointed out here that physiologists at the present day do not suppose such a membrane to be a permanent inert structure, but to be formed from the protoplasm in equilibrium with it and therefore liable to be affected by all kinds of functional change. Thus it becomes permeable in the state of activity of the cell, and most of Prof. Moore's arguments lose their weight.

There are certain interesting papers by the author which might well have been included in the present volume of reprints, such as those dealing with the osmotic pressure of colloids. This would have been a convenience to many workers.

When we find a section on the nervous mechanism of secretion amongst the questions dealt with in the book, we are naturally led to ask, what does the author understand by "biochemistry"? His biochemistry appears to be identical with what is properly called "physiology." The latter, however, as taught in the medical schools, is apt to be more or less limited to human or applied physiology, so that it was natural to institute a body of doctrine which should include the chemical phenomena of the lower animals and plants. But a complete physiological science includes these. Indeed, it is impossible to consider apart from one another the chemical and physical aspects of vital

[1] This review was written before the lamented death of Prof. Moore, the author of the work to which it refers.

phenomena. However convenient for practical purposes a separate department of biochemistry may be, it would be a matter for regret if this part of physiology became dissociated from the remainder. Indeed, it may safely be said that no physiological laboratory can carry on effectively any part of its work without the provision of a chemical department. Hence, biochemistry, as well as biophysics, must be included. What is needed seems to be the establishment of more chairs in what might properly be called "general" physiology, as distinct from "special" or human physiology. Since the term "general physiology" is sometimes misunderstood, and limited to the lower animals, perhaps the title of "biodynamics," suggested by the writer in another place, might be more appropriate. This name distinguishes the science of function from that of structure. Although, of course, one cannot exist apart from the other, such a separation is more scientific than that of the chemical from the physical departments of physiology, for the methods of both the fundamental sciences are needed for the proper investigation of vital problems.

At the same time, there may be said to be a more purely chemical branch of biochemistry, that devoted to the study of the properties of various compounds prepared from or by the living organism. This is really a special part of organic chemistry, and is obviously more related to the science of structure than to that of function, although it may conveniently be studied in connection with physiology. There is, however, an unfortunate tendency to call a man a "biochemist" who may be devoid of any acquaintance with vital phenomena. Another tendency, also apt to lead to confusion, is that of including pathological chemistry under biochemistry. This should surely be the chemical side of pathology, dealing with disease as physiology deals with normal processes. These remarks are not in any way intended to undervalue the pursuit of biochemistry, but as an attempt to make its position clear. Prof. Moore's book takes into consideration more than the chemistry of vital processes, so that the title is not altogether an appropriate one. W. M. B.

Morphological Aberration.

The Echinoderms as aberrant Arthropods. By Austin H. Clark. Smithsonian Miscellaneous Collections, vol. 72, No. 11. Pp. 20. (Washington, July 20, 1921.)

FOR some years past Mr. Austin Hobart Clark has been flirting with the idea that the Echinoderms were derived from the Arthropods, but we all pretended not to notice. Now that he has come into the open with a paper published by no less a body than the Smithsonian Institution, and that he has sent us a copy for review, we are obliged to reprobate such goings-on.

What Mr. Clark suggests is not merely such connection of the Echinoderma with the Arthropoda as others find with the Protochordata; he is "convinced that they are undoubtedly closely allied to the crustaceans, and especially to the barnacles." No one can have failed to remark some resemblances between crinoids and cirripedes, due to a somewhat similar mode of life: normally both are attached—whether by a stem or immediately sessile; the body is encased in plates, and from it project jointed and often branched appendages used for collecting food. It is not easy to gather precisely how much importance Mr. Clark attaches to these and other adaptive resemblances: we may give him credit for the statement that "there can be no question of any direct homology between" them, and confine him to the suggestion "that it is not impossible to regard them as parallel manifestations of the same ancestral appendicular plan." The trouble is that he will keep dragging in, not merely the highly specialised sub-class Cirripedia, but the most modified forms of that sub-class, thus:—"A combination of the asymmetry of the Verrucidæ [a geologically late family of cirripedes] (inherent also in very many other crustaceans, and especially noticeable in the Paguridæ and Bopyridæ [hermit-crabs and parasitic isopods]) carried to its logical conclusion in the complete atrophy of one side, with the modifications of the body seen in Sphærothylacus or Sarcotaces [problematic parasites] in a less extreme form, the roots of the Rhizocephala [parasitic cirripedes], and a skeleton formed after the manner of the plates in the shell of the Operculata [sessile barnacles of late origin], furnishes all the elements needed for recombination to form the crinoid." It is fairer to Mr. Clark to ignore these and similar comparisons of incomparables, and to consider only the fundamental parts of his argument.

The "outstanding features" of the echinoderms are, says Mr. Clark, "the presence of a vascular, a respiratory, and a superficial skeletal system, the last composed of articulated (calcareous) elements, the absence of gill clefts, and the sharp division of the body externally into (five radial) segments. In these features they agree only with the arthropods." Probably he means: "In the combination of these features." But, take the characters singly, and what is the resemblance? The so-called vascular system of echinoderms is most feebly developed and possesses no heart or other means of causing its contents to

circulate. The arthropods have a heart (except in some modified groups), a pericardium, and a large system of hæmocœlic spaces; the crustacea have definite arterial vessels. The arthropods, again, breathe by gills borne on the limbs or by tracheæ. But what Mr. Clark means by the respiratory system of the echinoderms is not clear: they aërate their body fluids in so many ways; such structures as papulæ, when developed, are not much like anything in arthropods. As for the crystalline skeleton of the echinoderms, deposited in the spaces of an interpenetrating mesoderm and resorbed as need arises, it can only be contrasted with the chitinous cuticle of the arthropods, hardened by the deposition of amorphous lime salts, and incapable of modification except through moulting. Lastly, how can the radial segmentation of echinoderms be homologised with the metameric segmentation of the arthropods? Mr. Clark does not tell us. He does, however, accept the general view that "the echinoderms are derived from bilaterally symmetrical ancestors," and he does later on quote Patten's hypothesis that the original metameres of the ancestor were suppressed on one side, and the remainder of the body bent round into a ring, so that the half metameres with their segmental organs became arranged in radiating lines—a hypothesis which places a very strained interpretation on the facts of embryology, and seems inconsistent with Mr. Clark's own views as to the relations of larva and adult.

No one would wish to assert that a study of the development and mode of life of the cirripedes can have no bearing on the origin of the echinoderms. There is much that is suggestive in the comparisons drawn by Patten and by Clark. But if those writers mean to conclude that the echinoderms were derived from the cirripedes by way of the crinoids, then assuredly they have been misled by adaptive resemblances. If they mean only that these resemblances imply a likeness of ancestral material no less than a likeness of external conditions, then we must ask them to indicate the connection between the ancestor of the Crustacea (nauplius-, Apus-, or trilobite-like, as they choose) and the bilaterally symmetrical ancestor (Dipleurula or what not) of the Echinoderma. It is quite possible that there was a primitive group of cœlomate animals from which the early echinoderms and the chætopod ancestors of the arthropods both arose; but to imagine that the arthropod type, once evolved on the "appendicular plan," as Mr. Clark calls it, retraced its steps towards anything that could have become an echinoderm, is contrary to all ascertained principles of evolution; and the alternative dream, that an arthropod, once recognisable as such, could progressively change into an echinoderm, is a baseless and unsubstantiated vision.

Mr. Clark will not, it is to be hoped, think we dismiss him in summary fashion. Many will say we ought to have done so. But there is a reason for treating the matter seriously. Any one has a perfect right to discuss the origin of the echinoderms and to maintain what views he pleases. Mr. Clark, as a distinguished authority on one class of echinoderms, certainly may claim a hearing. But whoever discusses morphological problems should have regard to the recognised principles and methods of morphology. He should have a sufficiently wide knowledge of comparative anatomy to be able to estimate the relative values of the facts that he adduces. There is at the present time a real danger that this discipline may be forgotten in the rush after alluring discovery in genetics, biochemistry, and other novel branches of biology. Among many examples of loose thinking in morphology, this of Mr. Clark occupies a bad eminence, exaggerated by the place of its publication and by the high merit of its author in his own field.

(1) MR. SOUTHERNS has faced the difficulty, which many university lecturers have experienced, of providing a course in physics for college students in their first year. Not only are there great differences in the preliminary knowledge with which the students are equipped, but also different groups—say, engineers and medicals—look at the subject from very different angles. The first year should be a year

of inspiration. Broad outlines should first be presented in an elementary but scientific manner. Part 1 of this book, which is intended to be used in conjunction with a theoretical text-book, aims at giving such a general sketch in which new knowledge is incorporated as an essential part of the course. Part 2 comprises a course of laboratory work suitable for general purposes. In an interesting preface Mr. Southerns has some suggestive observations as to the methods of dividing students into classes, with the view of allowing the better students to undertake more advanced work. Such subdivision is advocated in connexion with both tutorial and practical work. The book has been well thought out, and may be recommended to teachers who have similar problems to solve.

(2) In this new volume Prof. Ferry, who is known as the author of a useful handbook of practical physics, has placed teachers of physics under fresh obligation by providing a text-book for college students "in which especial emphasis is laid on the diverse relations of physics to Nature, agriculture, engineering, and the home. Much of the motivation and illustrative material has not appeared heretofore in any text-book." Even if we do not fully grasp what is implied by the term "motivation," we may admit the general accuracy of this claim. A lecturer on physics in search of novel or up-to-date illustrations should certainly consult this volume. By studying the series of kinetoscope photographs of a freely falling cat and the accompanying letterpress he will learn why the cat alights on its feet. "The recent war has produced many highly important and interesting devices, some of which are here presented to students for the first time." We find, for example, descriptions of acoustic goniometers, based on binaural hearing, for locating invisible submarines and aeroplanes, and of the "radio-compass," by means of which the position of a vessel at sea may be found by wireless signals.

The amount of information that has been packed into these 700 pages is remarkable. But it must not be supposed that this is merely a popular or descriptive book; it is a scientific treatise, and every page bears evidence of the fact that it is the work of one who has considered with care the theory of each subject and the best method of presenting it to the student. A few points of interest may be mentioned. For the familiar "latent heat of fusion" the term "heat equivalent of fusion" is suggested. The paragraph dealing with the black-body temperature scale seems to us to make a simple matter complicated by its treatment of "the black-body temperature of a non-black body." There seems no good reason for speaking or thinking of this as the temperature of the non-black body itself; it is simply the temperature of a black body which emits radiation at the same rate. Electric resistance is discussed before electromotive force or Ohm's law, being measured by the amount of heat developed in a conductor by the passage of unit current for unit time.

There are interesting chapters on the electron hypothesis (including a description of the three-electrode vacuum tube) and on electromagnetic waves. The section on light is excellent; the cardinal points and the aberrations of lenses and lens systems are well treated, as also are various optical instruments. Physical optics claims attention in three interesting chapters. The statement on p. 626 that it is impossible to have a blue sea when the sky is overcast has been contradicted recently by Prof. Raman (NATURE, vol. 108, p. 367). The volume contains numerous solved problems in the text, and nearly 700 unsolved problems with answers in an appendix; the illustrations deserve a special word of commendation.

(3) Space is lacking for a full account of the high ideals which have inspired the author of this manual. Suffice it to say that the physics course in a modern (American) high school "should proceed toward an organisation of practical situations, activities, and phenomena, the value of which will be recognised and approved by teachers, students, parents, administrators of education, and others who are responsible for the work which boys and girls do in the high school"! Hence these ninety-five "projects" include the construction of "a model of a kitchen hot-water heater" (*sic*); studies of methods of heating or lighting a room; experiments on electroplating, saucepan conduction, and wireless; studies of the camera, the kerosene stove, the phonograph, and the sewing machine; and lastly a section headed "automobile work" dealing with carburettors, ignition systems, and the engine of a Ford car. Here is a course "organised according to the recognised function of education in a democratic society"! We cannot help feeling a certain amount of envy of the boys and girls in the modern high school.

(4) Messrs. Haler and Stuart have produced an introduction to physics based on experiments which can be carried out with simple apparatus. The scheme is intended to cover a two-years course for technical or trade schools, when two or three hours a week are devoted to the subject. Questions and numerical exercises are plentiful. It is scarcely logical to say that the absolute zero of temperature would be reached at $-273°$ C. when the only scale of temperature that has been described is that of the mercury thermometer.

(5) Mr. S. E. Brown has prepared a useful course on light to occupy two terms for pupils about fourteen years of age. There are plenty of experiments and illustrations, and the Barr and Stroud range-finder is

shown as a frontispiece. Teachers will welcome the large collection of examples and revision questions.

(6) Part 1 of the "Elements of Natural Science" includes mechanics, chemistry, heat, properties of matter, light, and sound. With part 2 the course is intended to cover the "general science" syllabuses of School Certificate and Army Entrance Examinations. The treatment of the subject-matter, together with the experiments in illustration, should prove successful in exciting and maintaining the interest of the student. H. S. A.

Parasitism and Symbiosis.

Le Parasitisme et la Symbiose. Par Prof. M. Caullery. (*Encyclopédie Scientifique: Bibliothèque de Biologie Générale.*) Pp. xiii + 400 + xii. (Paris: Gaston Doin, 1922.) 14 francs net.

FEW zoologists are so well qualified as Prof. Caullery, who is editing the series of works on general biology to which the volume under notice belongs, to survey the range of parasitism and symbiosis. He is the pupil and successor at the Sorbonne of Alfred Giard, and like him is distinguished by a remarkable versatility, having brilliantly investigated the life histories of parasites belonging to many phyla. In his laboratory, too, there was largely carried out the work of Guyenot on aseptic life, which is fundamental for future attempts to solve the problems of symbiosis.

There are good modern treatises on medical parasitology, but these naturally concern themselves with a much narrower field than that required by the student of general biology for whom this book is designed. Throughout, it is characterised by an admirable lucidity, and the vast amount of information it contains does not interfere with the well-balanced arrangement. Recent research which has a general bearing on parasitism is presented with great care, and the bibliography is complete and invaluable.

Commensalism, parasitism, and symbiosis are dealt with successively as related phenomena. The series of more or less modified parasites which exist in many animal groups offer perhaps the most striking illustrations which can be given of the reality of evolution. Prof. Caullery has treated the groups he knows best in detail from this standpoint. The adaptation of the parasitic isopods (especially Entoniscidæ) to their diverse hosts, the evolution of the Rhizocephala in the cirripedes, and the clear series of parasites in the gasteropods are given the attention they deserve. There might also have been included with advantage an account of the passage in the nematodes from forms with a perfect alimentary canal through the intermediate group of the Mermithidae to those complete parasites which absorb food only through the skin.

Passing over the very useful chapters on the various types of parasitic life-history, the migrations of "heteroxenous" forms, and the adaptations for reproduction in parasites, there follows an interesting discussion of specificity of parasites, especially in connection with human interference with the distribution of insects and the parasites they convey. We miss a reference to the very rigid specificity which is stated to exist in the Mallophaga, occurring on birds. Here the association of host and parasite apparently took place at an early stage in the evolution of both groups, and the well-marked systematic relationships of the different Mallophaga actually throw light on those of the bird genera on which they are found.

In the chapters on symbiosis reviews are given of the large number of cases recently described where unicellular symbiotes are found in different invertebrate groups, and then of the extraordinary extension of research on these lines by Pierantoni and Portier. The claim of the latter that every living cell contains symbiotic organisms was seriously considered and rejected by a committee of French biologists, but interest in research on symbiosis is still intense in France. F. A. POTTS.

Our Bookshelf.

Anleitung zur mineralogischen Bodenanalyse. Von Dr. Franz Steinriede. Zweite umgearbeitete und erweiterte Auflage. Pp. viii + 240. (Leipzig: W. Engelmann, 1921.) 60 marks.

THE original appearance of this book in 1889 marked the first serious attempt to apply petrological methods to the study of the minerals of the soil. During the thirty-two years that have since elapsed, petrological methods have undergone considerable development, while, on the other hand, our knowledge of the soil has similarly been enormously extended. The development of these two subjects, however, has proceeded mainly on quite separate lines, particularly in this country, where soil investigators have studied chiefly the chemical and biological aspects of soil fertility. That our present methods of examination of soil frequently fail us in accounting for observed differences in fertility is an indication of the need for new methods of attack, among which mineralogical analysis is undoubtedly of importance.

The appearance of the new edition of a book by a pioneer in the subject is thus welcome, especially as no similar book exists in this country. The author gives a succinct but adequate account of all the important aspects of the subject, including elutriation and flotation methods of separation, optical and other physical as well as chemical methods of examination. The data for the application of these methods are collected in a series of useful tables, together with a

detailed classified description of all minerals likely to be met with in soils. Finally, there is a systematic scheme for the detection and identification of the commoner of such minerals, and a bibliography of 136 references. This book and its subject merit the attention of all soil investigators. H. J. P.

Webbia: Raccoltà di scritti botanici. Edita da Prof. U. Martelli. Vol. Quinto, Parte 1ª. Pp. 355 + xiii plates + maps. (Firenze: Mariano Ricci, 1921.)

THE portrait of Odoardo Beccari which serves as frontispiece to the most recent instalment of "Webbia" reminds men of science that the death of that eminent traveller and botanist at the age of 77, on October 20, 1920, meant the loss of the chief authority on the natural history of Palms. Much of this part (pp. 5-198) is devoted to two important articles left complete when Beccari died. A "Review of the Old World *Corypheæ*" is an epitome of the monograph prepared by Beccari for the Annals of the Royal Botanic Garden, Calcutta, in continuation of those on "Asiatic Palms" published in 1908 and 1911. An account of "The Palms of New Caledonia" is of exceptional interest because the palms of this group of islands, though few in number, are all endemic species.

In "La Culla del Cocco" (pp. 201-294) Prof. E. Chiovenda reviews the evidence available as to the home of the coco-nut. Historical and ethnological considerations may be adduced in favour of either the Asiatic origin accepted by P. Miller (1752), R. Brown (1818), and A. R. Wallace (1853), or the American origin suggested by von Martius (1840), considered at first by A. de Candolle (1855) to be probable, and regarded by B. Seemann (1873) as assured. The taxonomic judgment of von Martius turned the scale in favour of America until Beccari (1877) showed that this judgment was contrary to morphological facts. These facts, indeed, contraindicate an American origin so that Beccari suggested instead a Polynesian one, while A. de Candolle (1883), writing now "with more information and greater experience," favoured a Malayan rather than an American origin. The renewed advocacy of an American origin by Dr. O. T. Cook (1900 and 1910) left Beccari (1916) indisposed to modify his earlier view. Careful consideration of all the evidence leads Chiovenda to agree with A. de Candolle's later belief.

"Webbia" since its inception has contained many important results of Beccari's botanical studies, and the editor, Prof. U. Martelli, fittingly concludes this part with a sympathetic "Memoir" (pp. 295-343) of that eminent man of science, to which is appended an invaluable bibliography (pp. 344-353) of Beccari's contributions to botanical literature.

The Journal of the Institute of Metals. No. 2, 1921. Vol. xxvi. Edited by G. Shaw Scott. Pp. x + 760 + pl. xxxiv. (London: Institute of Metals, 1921.) 31*s*. 6*d*. net.

THE growth in size of the half-yearly volumes of the Journal of the Institute of Metals is a striking indication of the increasing attention that is given in this country to the study of the non-ferrous metals. The lecture on the casting of metals by Prof. Turner, which occupies the first place in the present volume, directs attention to the comparative neglect of this important subject of casting by scientific workers, in spite of the high degree of practical skill that has been acquired by foundrymen, proceeding by a method of trial and error. The remaining papers deal with varied questions. A note on the characteristic defect which appears in some bars of extruded brass led to an interesting discussion at the meeting of the Institute, in the course of which laboratory experiments with wax models were cited in illustration of the mode of flow during extrusion. A second note on the casting of brass ingots shows the desirability of an exchange of information between ferrous and non-ferrous metallurgists, the device proposed having been long adopted in steel works. Other subjects treated are gun-metal, cold-working, scleroscope hardness, nickel-aluminium-copper alloys, etching methods, and the properties of rolled zinc. An important research by Dr. Hanson and Miss Gayler definitely connects the ageing of duralumin and similar alloys with the varying solubility of magnesium silicide in aluminium. The number of abstracts shows an increase on previous years. C. H. D.

(1) *A Short Course in Commercial Arithmetic and Accounts*. By A. Risdon Palmer. (Mathematical Series for Schools and Colleges.) Pp. x + 171 + xv. (London: G. Bell and Sons, Ltd.) 2*s*. 6*d*.

(2) *The Use of Graphs in Commerce and Industry*. By A. Risdon Palmer. (Handbooks of Commerce and Finance.) Pp. ix + 47. (London: G. Bell and Sons, Ltd.) 2*s*. net.

(1) MR. PALMER'S books on the application of elementary mathematics to commerce and industry are a welcome addition to the literature on the subject. His "Short Course" is a brief account of the most important arithmetical methods and processes required in commerce. Those who know Palmer and Stevenson's "Commercial Arithmetic and Accounts" will expect to find the new volume useful and interesting, and they will not be disappointed. There is a touch of real life about most of the chapters, especially that on "The Home Trade": one only misses the Public Receiver and the creditors' meeting. But are contracted methods really used in commercial life?

(2) Graphical representation is a useful and important process in industrial and commercial life; its vogue is increasing, and we have already had the case of a Cabinet Minister using a graph in the House of Commons to illustrate the activity of his department. While the methods are not exactly the same as those used in mathematics as such, the ideas are of course similar. One often wonders whether and how the ordinary newspaper reader understands the diagrams used in connection with price fluctuations or statistical reports. Mr. Palmer's little book will certainly be useful to all who have to deal with such pictorial information: it is indispensable to the business man and economist.

The book is the third of a series of handbooks of commerce and finance. Co-ordinates are explained and applied to the broken straight-line diagrams used by commercial and other journals, and the rectangle method and the sector method of representation used in books on geography, economics, and commerce are then discussed. There are a number of useful exercises.

S. BRODETSKY.

Ministry of Munitions and Department of Scientific and Industrial Research. Technical Records of Explosives Supply, 1915–1918. No. 8: *Solvent Recovery.* Pp. iv + 22. (London: H.M. Stationery Office, 1921.) 3*s.* net.

IN the manufacture of cordite, which is the propellant used in practically all arms in warfare, a mixture of nitrocellulose and nitroglycerin is incorporated with a "solvent," consisting of ether and alcohol, and the doughy mass is extruded through dies to form the cordite strands. These are dried on trays in closed recovery stoves, where the solvent is evaporated in a current of warm air until only a small amount of volatile matter remains, which is finally expelled in drying stoves. The solvent-laden air may be treated in absorbers for the recovery of the solvents. The present report deals with the use of sulphuric acid, water, and cresol as absorbents, the last being found most satisfactory. The air and absorbent were brought together in a Whessoe scrubber, such as is used in gas works, and the solvent then expelled by distillation. Calculations dealing with the operation of the plant are given.

A Manual of Selected Biochemical Methods as Applied to Urine, Blood, and Gastric Analysis. By Prof. F. P. Underhill. Pp. xiv + 232. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1921.) 17*s.* 6*d.* net.

A COLLECTED account of the various ingenious methods devised by American workers in the field of urine, blood, and gastric analysis will be found in this useful laboratory manual. Although doubtless the methods are adequate for the purposes described, it is somewhat surprising to find no reference to the Barcroft apparatus for determining oxygen capacity, nor to the almost indispensable comparator of Cole or Walpole for use with indicators in coloured solutions. Mett's tubes require more cautious criticism in quantitative work than is suggested by the author. These are perhaps minor blemishes, and, apart from them, the book can be highly recommended. It is to be feared, however, that the price will militate somewhat against a large sale in this country.

The Commercial Apple Industry of North America. By J. C. Folger and S. M. Thomson. (The Rural Science Series.) Pp. xxii + 466 + xxiv Plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1921.) 18*s.* net.

A FULL account of the growing of apples on a commercial scale in North America is given in this work, and much information that could be obtained only with difficulty elsewhere is embodied in the text. It would prove useful to any English grower or student of horticulture who wished to obtain information as to the way in which this important industry is carried on. The authors state in their introduction that they have visited practically every important apple-growing county in the United States, first in connection with an investigation into the cost of production, and later in connection with attempts to organise a system for estimating the apple crop of the United States.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On Immediate Solutions of Some Dynamical Problems.

As a branch of science advances and its principles become more familiar to the mind of the investigator many things which before appeared involved and mysterious become simple and clear, and it is possible to find proofs of theorems so obvious and brief as to merit the name *intuitive* in a very real sense, though not that in which the term is frequently applied. For to say that a theorem or principle is intuitively perceived is often tantamount to saying that it is not perceived at all. By an intuitive proof of a proposition I mean a proof which is natural and direct, and it may be almost instantaneous in that the restatement of some element of the proof transforms the whole so that the proposition is at once recognised to be true. But the proof must be complete and rigid to be valid, and completeness and rigidity are qualities which have come to be almost denied by calling a proof "intuitive."

I have amused myself from time to time with endeavouring to devise what I venture to think are properly called *immediate* proofs of dynamical propositions, and some of these, with historical notes here and there, may be of interest to readers of NATURE. Many of the ideas of attractions have become so familiar, not to students generally by any means, but to those who have pondered over the connection between the theory of gravitational attraction and the mathematical theory of electrostatics for example, that the subject has acquired a very special interest and fascination to the minds of such workers. Accordingly I give here some propositions in attractions.

It is undoubtedly the case that Newton delayed the publication of the discovery of universal gravitation until he had discovered a proof which satisfied him that a uniform spherical shell attracts an external particle, as it would if the whole mass of the shell were comprised in a particle situated at the centre. For if this proposition were established, the earth, which there was reason to believe was a nearly spherical body with a distribution of density approximately symmetrical about the centre, would attract external matter as if its whole mass were collected at the centre, and this therefore was the point from which distances were to be measured in the numerical comparison of gravitational forces; for example, the comparison of the two unital attractions of the earth, that on a particle at the surface and that on the moon.

The proposition given by Gauss that the surface integral of normal force taken over a closed surface drawn in the field is equal to $4\pi k$ times the whole quantity of the attracting matter which is contained within the closed surface, is capable of many applications. This proposition may be more precisely stated as follows: Let dS be an element of area of the surface and N be the component of the field intensity at right angles to the surface (taken positive when acting outwards). Then the integral

$$\int N dS,$$

taken over the closed surface, is called the surface

integral of normal force, more properly normal field intensity, and we have the equation

$$\int N dS = k 4\pi M,$$

where M is the whole quantity of matter inclosed by the surface, and k is the so-called gravitation constant, the force between two unit masses at unit distance. Take an example: Let the field be produced by a uniform spherical shell of radius a, and describe a sphere of radius R concentric with it. Consider a point P on this sphere; the field due to the shell must by symmetry have the same intensity at every such point as P, and the resultant intensity at P, which we call F, must be at right angles to the surface; thus we have for the surface integral of normal force $4\pi R^2 F$; the whole quantity of matter within the surface if ρ be the density of the shell, and da the shell's thickness, is $4\pi\rho a^2 da$; thus by the theorem we have

$$4\pi R^2 F = 4\pi k(4\pi\rho a^2 da),$$

that is,

$$F = k\frac{4\pi\rho a^2 da}{R^2},$$

that is, the field intensity is the same as if the whole mass of the shell were collected at the centre.

The only parts of this proof which are not altogether satisfying are those which depend on considerations of symmetry; but it will be tolerably clear that any distribution of matter must attract a distant particle after the manner stated, and no valid exception to them can be taken.

I shall return to this theorem of Gauss for a proof of another proposition. No doubt it can be applied, though Gauss its discoverer does not seem to have done so, to establish other propositions in attraction. We may prove the proposition with which we have just been dealing by the following discussion, which shows that the *potential* of a spherical shell at an external point is the same as if the whole mass were collected at the centre of the shell. The idea of potential was given in the treatment of attractive forces set forth in the "Mécanique Céleste" by Laplace: the name *potential* was given by Green, who made considerable use of Laplace's idea. It is remarked somewhere, though I cannot remember by whom, that it is perhaps easier to show that the attractive *force* of a spherical shell on an external particle is the same as if the whole mass were collected at the centre than to prove the same proposition for the potential. The proposition for the attraction is proved in Thomson and Tait's "Natural Philosophy" (a classic which, like the other great treatises, nobody now has time to read) by a reference to the point which is the inverse,[1] with respect to the sphere, of the external point. The proposition is proved also by direct integration in the "Natural Philosophy." In a paper on the historically famous problem of the attraction of an ellipsoid I have shown how the reference to the inverse point, in the case of the sphere, may be dispensed with, and the proposition as to the force established by what is practically an instantaneous proof. I shall here modify the method to give a proof of the theorem of the potential. Use of the inverse point for the potential was first made by my friend Mr. C. E. Wolff, and I have here adopted his idea of dealing with the attractions of two elements at once, the two intercepted by a small cone with its vertex at the point which I call the point corresponding to the external point P. This is the point A in the diagram (Fig. 1) in which the line CP intersects the shell so that A and P correspond to one another, as do two corresponding points on confocal ellipsoids. Of course the concentric spherical surfaces on which P and A lie are a particular case of confocal ellipsoids.

Let the circle EAE_1 (centre C) be a section of the shell by the paper, and P be the external point. Through P describe a sphere, radius f, concentric with the shell. Consider an element of area dS of the shell at E. If k be the gravitation constant, and σ the surface density of the shell, the potential at P due to the element is $k\sigma dS/r$. Produce all the radii to the boundary of dS to meet the concentric spherical surface, and give a new element of area dS' ($=dS \cdot f^2/a^2$) on the concentric surface at E′. From the points of the periphery of dS' draw lines all passing through A. These lines will include a cone of small solid angle ω with vertex at A, meeting the outer surface in the two elements dS' and dS_1' at E′ and E_1' respectively. The element dS_1 at E_1

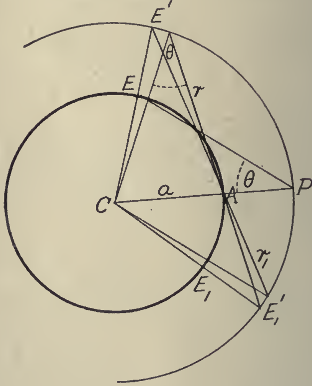

FIG. 1.

corresponds to an element dS_1' of the shell at E_1' at distance r_1 from A.

We have $dS' = \omega r^2/\cos\theta$, $dS_1' = \omega r_1^2/\cos\theta$.

The potential at P due to the two elements at E and E_1 is equal to the potential at A (the intersection of CP with the shell) due to the elements dS', dS_1' at E′, E_1', multiplied by the ratio a^2/f^2.

Thus if dV be the potential at P due to the pair of elements at E′, E_1' we have

$$dV = k\sigma\frac{a^2}{f^2}\omega\left(\frac{r^2}{r}+\frac{r'^2}{r'}\right)\frac{1}{\cos\theta} = k\sigma\frac{a^2}{f^2}2\omega f,$$

since $(r+r')/\cos\theta = 2f$. The potential at P produced by the whole shell is thus given by

$$V = k\sigma\frac{4\pi a^2}{f},$$

since the whole solid angle subtended at A by the external concentric sphere is 4π.

The proof of the theorem for the force is curiously different from that for the potential. Consider only a single element E in the diagram, and draw radii through all the points of the periphery of the element to meet the concentric surface through P; an element of this latter surface will be intercepted at E′. Let dS be the area of the element at E, and dS' that of the element at E′, and f the radius of the concentric sphere through P, and a as before the radius of the shell. We have then

$$dS = \frac{a^2}{f^2}dS'.$$

[1] The idea of using the inverse point in attractions of spheres seems to be due to Newton. See the "Principia," Book i., Proposition lxxxii., in which the attraction at an internal point of a spherical shell is deduced from that at an external point when the law of attraction is any function of the distance. In the text the law of the inverse square is alone considered.

Now from the diagram it will be seen that $\angle CE'A = \angle CPE = \theta$, say, and $EP = E'A = r$. The attraction due to E at P is equal to $k\sigma dS \cos\theta$, but this is clearly, if $r = EP$,

$$k\sigma \frac{a^2}{f^2} \frac{dS' \cos\theta}{r^2}.$$

Now the factor $dS' \cos\theta / r^2$ is clearly the solid angle subtended at A by the element dS'. The whole force exerted at P by the shell is thus, to a constant factor, equal to the solid angle subtended at A by the whole concentric surface of radius f, which is 4π. The attraction of the shell on a unit particle at P is thus $k4\pi\sigma a^2/f^2$, that is, it is the same as it would be if the whole mass were collected at the centre.

If the point P be internal to the shell the concentric surface with A falls within, and the total solid angle subtended by the shell at A is zero so that the attraction is zero.

This process extended to an ellipsoid and the confocal ellipsoid through an external point is made to give the force due to the shell at the point. The integration is made immediate by the use of a theorem of solid geometry which holds, as I pointed out, for confocal conicoids. The theorem may be stated here. Let A and P, E and E′ be pairs of corresponding points; then the distances AE′ and PE are equal, also if p and p' be the lengths of the perpendiculars from the centre on P and E′, θ the angle which PE makes with the perpendicular p, θ' the angle which E′A makes with the perpendicular p', then the theorem holds—

$$\frac{p}{\cos\theta} = \frac{p'}{\cos\theta'}.$$

This theorem shows the result of the integration over the ellipsoid to be, to a constant, equal to the solid angle subtended at an internal point by a closed surface in the manner just illustrated by the spherical shell. It is curious that this geometrical theorem which enables this result to be obtained is, as I have found, generally unknown to writers on geometry, and is not contained in any of the treatises which I have examined.

The next problem is one of which, I believe, the only simple solution given before 1900, was due to the late Prof. Tait, of Edinburgh. The problem was the determination of the pull between the two halves of a homogeneous sphere due to gravitational attraction. Prof. Tait's solution was a quasi-hydrostatic one, and I believe that he held the opinion that the only choice was between this and straightforward sextuple integration. There are, however, at least three other methods of attacking the problem, and one of these which occurred to me a long time ago I will indicate here. This has only been published so far as I know in a collection of exercises lithographed nearly twenty years ago by the late Dr. Walter Stewart, who was then my assistant, for the use of students in Glasgow. It makes use of the theorem of Gauss referred to above.

Consider the homogeneous sphere of radius a and let a closed surface be described consisting of a plane part dividing the sphere into two segments, and a spherical part fitting close to the smaller segment of the sphere. The surface integral of normal force over this surface will consist of two parts, I, the integral over the plane, and Σ the integral over the spherical portion. The mass M of the enclosed segment can easily be calculated and $4\pi k M$ is equal to $I + \Sigma$; of course Σ is also easily calculated, and thus I is obtained. If r be the radius of the plane section, z the distance of that section from the centre, ρ the density of the sphere, the mass of unit area of a disc of radius r and thickness dz is ρdz. Multiplying this by I, we see that the product $I\rho dz$ is the force due to the whole sphere on the disc of radius r and thickness dz, and if this be integrated from $z = a$ to $z = 0$ we obtain the attraction of the whole sphere on the hemisphere throughout which the integration has been carried; this attraction of the whole sphere on the hemisphere includes the attraction of this hemisphere on itself, which, of course, is zero. Thus the integration gives the attraction of one hemisphere by the other.

The mass M of the segment within the closed surface is easily seen to be

$$\frac{1}{3}\pi\rho(2a^3 - 3a^2 z + z^3);$$

the integral of normal force over the curved part of this segment is

$$\Sigma = 2\pi k a^2\left(1 - \frac{z}{a}\right)\frac{4}{3}\pi a\rho;$$

thus

$$I + \frac{8}{3}k\rho\pi^2 a^3\left(1 - \frac{z}{a}\right) = \frac{4}{3}k\rho\pi^2(2a^3 - 3a^2 z + z^3),$$

that is

$$I = \frac{4}{3}k\rho\pi^2 z(z^2 - a^2).$$

We have therefore for the product of I by the mass per unit area of the disc coinciding with the plane surface of the segment

$$I\rho dz = \frac{4}{3}k\rho^2\pi^2 z(z^2 - a^2)dz.$$

Integrating from $z = a$ to $z = 0$ we get for the pull P on one hemisphere exerted by the other,

$$P = \frac{1}{3}k\pi^2\rho^2 a^4,$$

or $3kM^2/16a^2$, where M is the mass of the sphere supposed of uniform density ρ.

A numerical estimate of P for the earth must be very rough, for the earth is not of uniform density, and there are other causes of inexactitude. But by the formula an estimate can be made in any units that may be preferred. In c.g.s. units k is $6{\cdot}7 \times 10^{-8}$. The force between the two hemispheres of a body of such great dimensions as the earth must be almost entirely due to gravitational attraction (for cohesion must be negligible in comparison), and this figure may be taken as giving an idea of its amount.

ANDREW GRAY.

The Conquest of Malaria.

THE obituary notice of Sir Patrick Manson, in NATURE of May 6, concludes with the hope that his memory may ever be kept alive as the Father of Tropical Medicine. As to this it is not difficult to forecast that the medical profession will fully concur. To the enthusiasm and inspiring teaching of Manson is due the existence of tropical medicine as a speciality, and the ever extending benefit tropical races receive at the hands of men trained on the lines indicated by him.

In the present day, the views of the medical profession are apt to change rapidly in accord with accumulated investigations and experiences of world-wide origin; opinions rigidly adhered to for fifty years may be rendered taboo by a single telegram received from some expert at a remote corner of the earth. If the new view stands the test of criticism the practical results are grasped; but few care to memorise how the change was effected. If this be so with the profession specially concerned with disease

prevention, it is not surprising to find that certain lay journals, in their biographical notes of Sir Patrick Manson, have given erroneous views of his connection with malaria prevention. Although, obviously, the well-informed writer of the obituary notice in your columns has no such intention, it seems to me that his quotation from NATURE (Vol. 61, 1900, p. 523) of matter by Sir Ronald Ross, unless considered side by side with other historical facts, is liable to accentuate the popular assumption that Ross, having been instructed by Manson as to what he would find in the mosquito, forthwith[1] performed the necessary hara-kiri—and the key to the etiology of malaria was found; and, therefore, to Manson and not to Ross is due the credit of the epoch-making discovery of malaria transmission. Yet Manson, with no less courtesy and frankness than displayed by Ross in elevating (in the matter quoted by your writer) what Manson himself termed a hypothesis to the rank of an induction, expressly disavowed any such claim.

In thus acting, Manson was fully aware of the great value to the British Empire and the world generally of the solution of the malaria problem which had been secured by Ross. In his paper read before the Royal Institute of Public Health Congress at Aberdeen, in 1900, he said: "I feel safe in asserting that malaria is far and away the most important of the many problems of tropical empire—that empire on which so much of our present and of our prospective national prosperity depends. The politician and the soldier may not think so. They are wrong. Such people habitually magnify their offices. . . . Our little wars and rebellions in their effects and importance are insignificant in comparison to the great natural phenomena, disease—to malaria for example." "My purpose . . . is to state . . . the . . . leading facts of the new knowledge which dawned only some twenty years ago with the discovery by Laveran of the cause and nature of malaria, and which culminated only two years ago when our countryman Ross showed how the infection is acquired, and in doing so clearly indicated in what way it is to be prevented."

To understand Manson's position it is necessary to indicate what was the actual "induction" he placed at the disposal of Ross. The following is found at pp. 16 and 17 of the first edition of "Tropical Diseases," by Manson: "I consider that the flagella—which as already stated are to be regarded as flagellated spores (*sic*)—are endowed . . . with locomotive powers, in order that they may be able to pass from the blood in the mosquito's stomach to the tissues of the insect. . . . The plasmodium, I hold, is an intracellular parasite both outside as well as inside the human body, and that when outside the human body it is parasitic in the mosquito. . . . The mosquito generally dies in the water beside the eggs she has deposited. When the eggs are hatched the young larvæ commonly devour the body of the parent and consequently her parasites. On the infected larvæ becoming mature insects the plasmodia they have swallowed continue, I conjecture, to develop. These insects, in their turn, infect their larvæ and so on. . . . *Man, I conjecture, may become infected by drinking water contaminated by the mosquito; or, and much more frequently, by inhaling the dust of the mud of dried-up mosquito pools; or in some similar way.*" (Italics not in original.)

Whilst, then, it is true Manson's induction of 1894 strengthened the hypotheses of Dr. A. F. A. King and Laveran as to mosquito agency, and this resulted in an inquiry by Ross as to possible extra-corporeal existence of the plasmodium, it is equally true that the work of Ross proved Manson's theories in essential details incorrect and misleading.

[1] Unaided by public funds, Ross devoted years of laborious experiments to the solution of the problem.

Holding in mind the Manson hypothesis, as stated by himself, if the quotation used by your writer be placed side by side with Manson's disavowal, it is not apparent there was any intention of Ross to say more than that the Manson hypothesis proved an incentive to action, and that in its absence it is probable research on the subject would have lapsed:

Ross.	Manson.
(Vol. 61, 1900, p. 523.)	("Tropical Diseases," ed. 1900, p. 21.)
"I have no hesitation in saying it was Manson's theory, and no other, which actually solved the problem; and, to be frank, I am equally certain that but for Manson's theory the problem would have remained unsolved at the present day."	"Thus by direct observation and analogy Ross distinctly, and first, proved that the extra-corporeal phase of the malaria parasite is passed in particular species of mosquitoes, and, by analogy, that the parasite *is transferred from man to man by the mosquito.*" (Italics not in the original.)

It need not be said that sanitary efforts based upon the mosquito contamination water theory of Manson could have secured no conquest of malaria.

W. G. KING.

Transcription of Russian Names.

THE system for transcribing Russian names advocated by Dr. Bohuslav Brauner in the issue of NATURE for April 29, namely, by the adoption of a few letters from the Bohemian alphabet, is open to serious objection.

In the first place, Bohemian is not the only Slavonic "State-tongue of an independent State." If Russian is to be transcribed into Latin characters as used by Slavs, the obvious model is Serbo-Croatian, which employs both Cyrillic and Latin characters, with regular rules for transcription. The Bohemian and Croatian alphabets are by no means identical; for instance, *ch*, which has in Bohemian the same sound as in German and Gaelic, would convey to a Croat some such sound as *tskh*; and he would not recognise some of the Bohemian letters bearing diacritical marks.

But if we are trying to abolish the Germanised and Gallicised forms of Russian names, why substitute another foreign form? These Slavonic letters with the diacritical marks are as unfamiliar to the ordinary Briton as the Cyrillic letters themselves,—*vide* Dr. Brauner's examples; and from this follows a practical difficulty in adopting his system in this country, namely, that very few printing presses and certainly no linotype machines have the necessary type, and the cost of introducing it would be prohibitive. Thus Dr. Brauner's "advantage of a great economy in printing" is outweighed by the disadvantage of impracticability in printing.

There is no reason why Russian personal names should not fall into line with Russian place-names, many of both being identical. And for Russian place-names the Permanent Committee on Geographical Names for British Official Use has adopted the system that has been in use for many years at the War Office, and also, except in one or two particulars, at the Admiralty. This is a system of transcription without the use of diacritical marks, which are undesirable in maps; the vowels have Italian values (e.g. *e*, *i*, *u*), and the consonants English values (e.g. *ch*, *sh*, *y*), the only exception being *j* which has the French value and is preferable to the un-English *zh* for this sound. If

it is desired to represent the Russian "soft sign," the apostrophe may be used. To take Dr. Brauner's examples, the Permanent Committee for Geographical Names would write Chicherin, Jemchujni, Mendeleev, Kon', Tatyana, Pushkin, Dyadya, Mechnikov.

Complete tables, not only of transcription from Russian but of the English values of other European and Near-Eastern alphabets, may be found in "Alphabets of Foreign Countries transcribed into English according to the R.G.S. II. System," recently published by and now obtainable at the Royal Geographical Society.

The Helmholtz Theory of Hearing.

DR. E. W. SCRIPTURE, in his letter on the above subject in NATURE of April 22, p. 518, has dealt with the case in which the note is continuously *changing*, and shows that when this is so every resonance organ of the ear must act at every instant for every vibration of the voice. Now suppose a pure fundamental note (*i.e.* one without harmonics) to be started and continued. At the start it would, on the principle of the apparatus designed by Dr. Hartridge, cause *all* the resonance organs of the ear to act, and we should hear a certain quantity of sound. Then gradually all, except one, of the resonance organs would cease to act, and we should hear only by means of the one which was synchronous with the pure note, and if this were so, presumably the quantity of sound would then appear to us much less than at the start. Has such an effect ever been recorded? If not, there would appear to be something wrong with the hypothesis.

A. S. E. ACKERMANN.
17 Victoria Street, Westminster, London, S.W.1, April 27.

PROF. SCRIPTURE has advanced in his letter in NATURE of April 22, p. 518, an argument which, if it were sound, would indeed necessitate the abandonment of the resonance theory. He must, therefore, excuse me if I point out what I consider to be the weak links in his chain of reasoning.

The first statement in his letter with which I find myself at variance is that according to the resonance theory only one resonator should respond to one tone. This is not only in disagreement with what Helmholtz wrote, but is also in disagreement with experiment. The resonance model referred to by Prof. Scripture, of which a photograph is reproduced in Fig. 1, showed that beside the intune resonator marked C being in vibration, there is also obvious movement in the one to the right-hand side as well. If there had been other pendulums of intermediate length mounted on either side of "C," there is no doubt that a number of these would also have been set into vibration, the actual number varying with the degree of damping applied to each. Helmholtz worked out the case of the ear resonators by means of calculations which appear to apply equally to all types of oscillating systems. He estimated that for tones about the middle of the musical scale, resonators having natural periods different from the incoming vibration by one semitone would be performing forced vibrations, the amplitudes of which would be approximately one-tenth that of the strictly intune resonator.

Now I have already stated (*Brit. Journ. Psych.*, April 1922, p. 370) the reasoning on which is based the estimate that some 600 resonators correspond to each octave in the musical scale. One semitone on either side of the intune resonator would, therefore, include about 100 resonators, and all these must be vibrating with one-tenth the amplitude (or more) of that of the intune one.

We see then how completely this estimate is at variance with Prof. Scripture's suggestion that according to the resonance theory only one resonator should be in vibration.

The second statement with which I cannot agree is that every vibration in a glide (since each vibration is different from the one which preceded) or every

FIG. 1.

spoken word (since the voice tone is continually changing) must therefore set every resonator into motion from the highest to the lowest, and I have never observed any behaviour on the part of my resonance model which would give any basis for such a supposition. I have attempted to calculate what would happen to a series of resonators which are set into vibration, not by a fixed tone, but by a tone changing in pitch. I find that, as in the case of a fixed tone, a group of resonators is set swinging, but that this group is larger than that set swinging by a pure tone, and I infer that the centre of this group moves up the scale with the same rate per second as does the incoming sound, but with a small time lag. For example, if the pitch of the tone is changing by as much as one octave per second the group of resonators appears to be only two or three times as large as that set swinging by a pure tone. Presumably then the tone will be quite recognisable, although it will not have the purity that a fixed tone possesses. This latter effect may possibly be correlated with the unpleasant character of a rapidly changing tone, *e.g.* the commencement of a steam syren blast. Whereas there does not appear to be any evidence at present by which the above estimate can be checked, yet I think that it must be at variance with the facts to state, as Professor Scripture has done, that when the pitch of the incoming vibrations vary, all resonators irrespective of length must be set equally into vibration.

I regret that it was my model which raised these doubts in Prof. Scripture's mind concerning the resonance theory. I should have made it quite clear to him that there was roughly a semitone difference of pitch between each pendulum and its neighbour. The model was not designed to demonstrate the better-known phenomena of resonance, but to elucidate the effect of interrupting temporarily a musical tone; for this purpose a few rather widely spaced pendulums sufficed. If the number of pendulums in the model had approximated more closely to the number apparently to be found in the ear, then Prof. Scripture would, I feel sure, never have criticised the resonance theory as he has done.

H. HARTRIDGE.
King's College, Cambridge, April 26.

Directive Radio-telegraphy and Navigation.

In foggy weather, sound-signalling stations have proved useful as an aid to navigation. The sounds heard, however, cannot be trusted to give accurate indications either of the distance or direction of the station. Their range also is very limited. It is not surprising, therefore, that many suggestions have been made for utilising the electric waves used in radio-telegraphy to enable a navigator to find his bearings. The propagation of electric waves is unaffected by fog and, unlike sound or light waves, can be transmitted to any distance. Moreover, the apparatus required for radio-signalling is very cheap, requires little skilled attention, and can easily be installed in lighthouses and lightships. Until two or three years ago the radiophares—or radio-beacons as they are called in America—were purely stations for giving ships their positions. In order to find its bearings a ship must send a message to two or more stations, and its direction is located by direction-finding coils. The stations then communicate with one another and so, by the help of triangulation, find the position of the ship, which is communicated to it by radio-telegraphy. In practice the whole operation takes about five minutes. The most extensive chain of direction-finding stations is that controlled by the United States Navy. There are at least thirty stations on the Atlantic seaboard and several on the Pacific coast. France has about ten radiophares and this country has six. A drawback to the method is that valuable time may be lost in getting into communication with the radiophares and in getting the information back to the ship.

A new and very promising method has been recently developed by the Bureau of Standards at Washington in co-operation with the Bureau of Lighthouses. In this method lighthouses and lightships the locations of which are accurately shown on sailing charts are equipped with radio fog-signalling apparatus. A direction-finder operated by the navigating officer is installed in the ship. It is then easy to find the directions of the various radiophares within his range and thus work out his position on the chart. The results obtained by this method have been very successful, and it seems to be much preferable to the ordinary method of using the direction-finder at the fixed stations. It seems probable that every important lighthouse in America will soon become a radio fog-signalling station. The Bureau of Standards suggests that radiophares should be divided into three classes. The first, or long-range class, has a radius of action of 300 miles. The second, or short-range class, can signal to 30 miles; and the third class comprises the lightship stations which can signal to 10 miles.

The method has been made possible by the perfecting of a new radio direction-finder. The principle on which it acts is that the signals received by a flat coil have their maximum intensity when the direction from which they come is in the plane of the coil. When certain precautions are also taken in arranging the apparatus, the signals are of practically zero intensity when the plane of the coil is perpendicular to the direction from which they come. As Fig. 1 shows, it is designed to be installed over the ship's binnacle carrying the magnetic compass. The radio-bearings are read directly on the magnetic compass card. An additional scale, marked with the corrections obtained when calibrating the instrument, is attached to the top of the binnacle so that the true reading can be obtained at once. When taking a bearing the only operation necessary is to rotate the direction-finding coil until the sound is a minimum. The ordinary type of direction-finder for use on shipboard consists of a coil of ten turns of insulated copper wire wound on a wooden frame four foot square, which is mounted so that it can be rotated about a vertical axis. Suitable receiving apparatus is used in connection with this coil, namely, a variable air condenser for tuning purposes, a six-tube amplifier having three stages of radio-frequency amplification, a detector, two stages of audio-frequency amplification, batteries, and suitable telephone receivers.

Fig. 1.—Magnetic compass with direction-finder attachment for reading the radio-bearing directly on the magnetic compass.

The Bureau of Standards have issued a pamphlet by F. A. Kolster and F. W. Dunmore giving a full description of the direction-finder, pointing out some of the difficulties that had to be overcome in developing it, and giving many experimental results.

The Cause and Character of Earthquakes.[1]

By R. D. Oldham, F.R.S.

The study of earthquakes, using that word in the restricted, and original, sense of the disturbance of the ground which is sensible to human feelings, which causes alarm and destruction, and is properly that seism of the ancient Greeks, from which our modern term seismology is derived, has always been recognised as one of the departments of geology. This limitation is necessary, for, of late years, seismology has been extended to the study of a phenomenon of different character, the long-distance records of dis-

[1] Abridged from the presidential address delivered before the Geological Society of London on February 17.

turbances, only to be detected by very sensitive instruments of special construction; in some cases these are clearly connected with great earthquakes—as the word is here used—and by inference have been presumed to be so in all cases, even when there is no independent evidence of the earthquake proper. The records, regarded as records of the progressive enfeeblement of the larger disturbance of the true earthquake, would represent the cryptoseism, or unfelt earthquake, and be described correctly in the observatory records as earthquakes. That they are correctly so described is indisputable, if the word is taken in its literal interpretation as a quaking, however feeble, of the earth; but if the implication is added that they have the same origin as the greater disturbance, the correctness of the description becomes doubtful.

Some dozen years ago the results of a study of the records of the Californian earthquake of 1906 led me to point out that, while the immediate origin of the earthquake proper may be traced to occurrences which take place in the outermost parts of the earth's crust, these are but the secondary result of a deep-seated origin, or bathyseism, which gives rise, at the same time, to the disturbance which is recorded at long distances by suitable instruments. Later work and research has more and more confirmed both the correctness of this interpretation and the conclusion that the proximate cause, of great and destructive earthquakes, is distinct from that of the long-distance records, though the two origins are connected with each other as effect and cause.

In the present state of our ignorance of the nature of the bathyseism, it is difficult to give a clear and precise definition of the mode of connection between it and the earthquake proper; the subject is an interesting one, and a review of the evidence, together with the deductions which can be drawn from it, would fill the time available, but it is not my intention to do more than to attempt, by analogy, to illustrate and explain the nature of the connection of the bathyseism with its two independent results.

Not many years have passed since, in the south-eastern corner of England, we heard what were known as the guns of Flanders; and the description was correct. The sound—it was more a sensation than a sound—which was heard in Kent and Sussex was undoubtedly produced by the report of great guns, by the explosion, that is, of the charge in the gun itself; but had the explosion done no more than give rise to the sound waves which travelled far in every direction it would have little troubled the enemy. Simultaneously, however, with the production of the report, and by the same explosion, a projectile was sent flying through the air which exploded after a trajectory of some miles, causing the damage which was the purpose of its despatch. The effect of this second explosion was severe but local, and at a short distance away neither sound nor shock was sensible.

Here we have a very complete analogy; the explosion of the gun represents the bathyseism; the report and sound waves travelling afar, correspond to the disturbance which, propagated through the substance of the earth, gives rise to the long-distance records: the explosion of the shell to those dislocations in the outer crust which produce the destructive earthquake; and the trajectory to the connection, of which the character is as yet unknown, between the bathyseism and the surface shock.

If this interpretation be accepted, it becomes evident that the distant records represent something which is distinct from the earthquake, as originally understood, and that the study of records, with the deductions drawn from that study, have little or no bearing on the problems of geology, as we usually limit the scope of that science. It is otherwise with the earthquake proper; originating in, and affecting, the outermost crust of the earth, it has long, and rightly, been regarded as one of the departments of geology, both as regards cause and character, and it is with this aspect of the subject alone that I shall deal.

The character of earthquakes is known to an extent sufficient for my purpose; they are elastic waves, transmitted through the substance of the earth, not, as was once supposed, merely waves of elastic compression, but of most complicated character, and, in all but a small minority of cases, nothing but this vibratory movement, the orchesis, can be recognised. Occasionally, however, and only in the case of some earthquakes of destructive violence, there is also a bodily and permanent displacement of the solid ground, and this mass, or molar, movement has been distinguished as the mochleusis of the earthquake, as distinct from the elastic displacement, accompanied by return to the original position, which constitutes the orchesis. Now the elastic waves can only be initiated by some sudden impulse or disturbance, such as might be produced by the fracture of rock, and as, in those earthquakes where mochleusis can be recognised, there is usually evidence of sudden movement along some pre-existent fault-plane, or of rending and fissuring of the solid rock, faulting or fracturing has come to be regarded as the cause from which the vibratory disturbance, propagated through the unfractured rock, originates.

This conclusion is supported by the fact that the proximate origin of the shock can almost always be placed at a moderate depth from the surface. It is, unfortunately, impossible to give any precise figures, for none of the methods which have been suggested for determining the depth of the origin can be trusted, some because they depend on assumptions which the progress of knowledge has shown to be erroneous, others because they demand data which cannot be supplied with the requisite precision, if at all; but there is another way in which some idea of the depth of origin may be reached, based on the fact that there is usually a well-defined area of maximum intensity of shock, surrounded by regions of diminishing intensity, as the distance from the central area increases. Since the violence of the disturbance will decrease with the increase of distance from the origin, it follows that, the nearer the origin lies to the surface the more closely does the variation of surface distance from the epicentre approximate to the variation in actual distance from the origin; hence it is evident that the rate of variation of intensity of the disturbance will give some notion of the depth of the origin. In this way, quite apart from any numerical estimates which have been made, it becomes clear that, excluding a small minority of earthquakes which will be referred to later, the origin lies

at a very moderate depth below the surface, probably seldom over ten miles, and usually less, that is to say, within the limits of the solid outer crust of the earth; and in this region it is difficult to conceive of any cause, sufficient to originate the elastic wave-motion of the earthquake, other than the sudden fracture of the solid rock, where strain has outgrown the power of resistance.

Apart from this general reasoning from observation, there are cases on record where considerable displacements of the ground have been measured by the comparison of careful and accurate surveys made before and after the earthquake. In three of these—the Cutch earthquake of 1819, the Sumatran of 1892, and the Californian of 1906—the largest movements took place close to the line of fracture, and in opposite directions on opposite sides of it, the displacements decreasing on either side till a region was reached in which no change, from the condition before the earthquake, could be recognised. As this is precisely what would take place if a solid body, capable of elastic deformation, was strained until fracture took place, the conclusion is justifiable that such was in fact the origin of the dislocation and displacements.

So far the conclusions, which may be drawn from observation, as they have been briefly outlined, belong rather to the domain of physics than of geology, but when we go on to consider the cause to which the strain is to be attributed, and more especially the rate of growth, we are brought into contact with problems and deductions which are intimately connected with geology proper, and to which I propose to confine attention in the remainder of this address. As regards cause: this is usually attributed to what are known as the tectonic processes, a term which may approximately be described as the processes by which the folding and faulting of rocks were produced, and, in accordance with this attribution, the class of earthquakes with which we are concerned is referred to as tectonic. The rate of growth of strain has almost invariably been accepted as very slow, yet when the subject is looked into, it will be found that there is really no evidence to support the acceptance; in part it must be attributed to the general belief that all geological action is necessarily slow, and in part to the conclusion that the Earth is a solid inert and highly heated body, cooling slowly by radiation, with the subsidiary deduction that all deformation of the outer crust must be referred to contraction, consequent on that slow cooling. The latter of these reasons is now abandoned by those who forced it on us, and the former, though true in general, must not be treated as an unchangeable law, for there are many cases where a process, slow on the average, and as a rule, is occasionally subject to temporary acceleration of rate. The evidence, too, which has been regarded as confirmatory of the slow growth of strain, is, in truth, more properly described as an interpretation of observed facts in accordance with an hypothesis.

In the report on the Californian earthquake of 1906, for instance, the displacements caused by that earthquake and an earlier one in 1868 are explained by a slow growth of strain, extending over a century or so, partly relieved by fracture in 1868, and again in 1906. The argument is conclusive in so far as it shows that the effects are consistent with the hypothesis, but it was not noticed that they would be equally consistent with a condition of quiescence throughout the whole period, with the exception of two short intervals immediately preceding the two shocks, respectively. The same may be said of all the supposed evidence in favour of a slow growth of strain; it is true that in those earthquakes which have been investigated in detail, and in which the observations allow of any definite conclusion, the indications point to the conclusion that the proximate cause is fracture resulting from excessive strain, but there is in no case any evidence of the rate at which that strain accumulated; nor is it possible that any such evidence could be found. The after-effects may satisfactorily establish the conclusion as to the cause, but they can give no indication of the time occupied in preparation; the earthquake comes and passes, it leaves certain records behind it, but these records would be the same whether the preparatory growth of strain was secular or instantaneous in duration.

Yet the problem is not insoluble, for there is another line of attack, which has only become practicable within the last few years. If we regard the growth of strain as continuous, there will be a certain increment which will lead to fracture, earthquake, and partial relief; then with a further increment the process will be repeated, and so we reach the concept of a mean-strain interval for each shock, which may be regarded as constant, on the average, for any given region, provided that the average is taken over a sufficiently long period. Any variation in the rate of growth of strain must be accompanied by a corresponding variation in the frequency of earthquakes. We have, then, four quantities so related to each other that if three of them are known the fourth can be determined. Of these four, two, namely the mean frequency and the variation from that mean in any chosen period, can be obtained from observation, and if the variation from the mean rate of growth of strain is also known, for the selected portion of the whole period, that mean rate which is the object of search can be obtained by a simple rule of three sum. So that if there were any external cause which, acting periodically and alternately in increase and decrease of the rate of growth of strain, and if it were possible to disentangle the variations due to this from those due to other causes, we would have a means of framing a numerical estimate of the general rate of growth of strain.

One such cause of periodic variation is to be found in the tide-producing stresses set up by the sun and the moon. It is true that many attempts have been made at different times to detect some connection between the frequency of earthquakes and the position of the moon, and that no such connection has yet been established, but these attempts have all been based on very imperfect records. In time it may, perhaps, be possible to apply to an earthquake record the method of harmonic analysis, which has proved so fertile in the case of the ocean tides, but the day is long distant when a record of sufficient completeness will be available. Meanwhile there are some simpler relations, of

which a discussion is feasible, and the most promising of these seems to depend on the fact that the downward pressure is greatest at the time when the attracting body is on the horizon, and least when it is on the meridian. If, then, we divide an earthquake record into two groups, one containing all shocks which occur within six hours before a meridian passage, and the other all that happened within six hours after, one of the two groups will cover a period during which the downward pressure is, on the average, increasing, while the other will cover the period during which it is decreasing. As the amount of the change so introduced is known, with sufficient accuracy for the present purpose, and as it should, on the hypothesis being used, influence the frequency of earthquakes, it follows that we have here a method, which should enable us to make an estimate of the rate of growth of the strain, to which fracture is due.

Although simple in principle, the method is difficult in application. To begin with, a record is required of sufficient extent and continuity to give a trustworthy average, not merely of the general frequency, but also of the frequency in each of the two sections into which it is divided, and this in practice means that the record must contain at least two thousand shocks and ought to contain double that number or more. Then it must be reasonably accurate as to times and complete as to occurrences, or at least must be fairly uniform in its incompleteness over the whole period investigated. There are not many records which fulfil these primary requirements, but there is another even more important. In all records there is a noticeable variation in frequency at different times of the day, moreover, the nature of this diurnal variation has been found to vary in different regions, but appears to be constant and characteristic, in each region, over the period of record. The cause of this periodicity may reasonably be attributed to some effect, meteorological or other, connected with the daily course of the sun, but its nature, no less than its variability, shows that it can only be attributed in part, if at all, to gravitational attraction. It is only, therefore, by a conversion of the record from solar to lunar times that the influences of these other effects can be eliminated, and the gravitational attraction of the moon be detected and estimated, and, for the satisfactory application of this method, it is necessary that the record should cover a complete lunar cycle, or a period of nineteen years. There are only two records extant and available which fulfil this requirement, and of these the Italian is not only the most complete and accurate, but is the only one to which the conversion into lunar times has been applied.

From the summary of the figures obtained, published in our Quarterly Journal, it appears that in the six hours preceding and following a meridian passage the mean departure, from the general average for six lunar hours, is almost exactly 1 per cent. of the mean.

Passing over details of calculation, the average rate of growth of strain is found to be such that the breaking point would be reached in about two months from the start, with a wide variation on either side. Some other relations between the frequency of earthquakes and the diurnal variation of the tidal stresses might be, and have been, investigated; all give fairly confirmatory results, the longest period indicated as required for reaching the breaking strain being just about a year.

It must not be supposed that value can be attached to the precise figures. As is invariably the case, in all calculations regarding physics of the earth, many considerations are involved of a very uncertain nature, but the reasoning does show that the increase of strain must have taken place at such rate that the breaking point was reached in a period measurable at most by months, and shows that the period could not have been of such length as to be measurable by years or decades, for, had this been the case, the disparity dealt with would have been much greater than that actually found.

Obituary.

PROF. G. S. BOULGER.

BY the death of Prof. G. S. Boulger on May 4, botanical science has lost an accurate and advanced observer who did much to popularise the study of his favourite science, and left his impress on several generations of devoted students. He was an active botanist to the end. On April 26 he attended, as chairman, the meeting of the Botanical Section of the South-eastern Union of Scientific Societies, and he himself was struck by the difficulty in breathing which he experienced in mounting a number of stairs to the meeting-room. Almost his last words on his death-bed had reference to the preparation of the report to be presented to the Congress of the Union at Southampton in June. He died literally in harness.

Prof. Boulger was born in 1853, and was educated at Wellington and Epsom Colleges; at an early age he became Professor of Natural History at Cirencester College, holding the chair for thirty years. Among other appointments which he held were those of professor of geology and botany at the City of London College, and in recent years he was a guide at the Imperial Institute. But his students were a wider public than institutions afforded. He was in considerable request as a public lecturer, and frequently visited, as such, various local natural history societies. He was closely connected with the Selborne Society, of which he was a vice-president, and the magazine of which, *Nature Notes*, he edited for some years. In recent years he was much interested in what has come to be known as Regional Survey, and in this connection did good work for the Gilbert White Fellowship, an up-to-date survey of Selborne being now in progress.

As an author Prof. Boulger had an attractive style. For some time he edited the Proceedings of the Geologists' Association. His knowledge of geology enabled him to throw considerable light on the origin of the British flora. His "Biographical Index of British and Irish Botanists," with Mr. J. Britten, is a valuable book of reference. His "Familiar Trees,"

and "The Country Month by Month," with J. Owen (Mrs. Owen Visger), brought him into touch with a wide public, and his edition of Johns' "Flowers of the Field" has proved invaluable to thousands of amateur botanists. Other works of his were "The Uses of Plants," "Elementary Geology," and "Plant Geography." He was for a long time the Kew Gardens correspondent of the *Times*. He always faced troubles cheerfully, and, constantly active, it is to be feared that overwork may have had much to do with his regretted death. His loss will be greatly felt by workers in many fields.

By the death of Dr. C. W. Waidner on March 10, the Bureau of Standards lost the third member of its original staff within the last year. Dr. Waidner was born in Baltimore in 1873, graduated at the Johns Hopkins University in 1896 and remained there, engaged first in research and afterwards in teaching, till he was appointed to the staff of the Bureau on its foundation in 1901. In a short time he became head of the Heat and Thermometry department, and organised the testing of thermometers of all kinds from clinical instruments to optical pyrometers. In conjunction with various members of his staff—most often with Dr. G. K. Burgess—he published a number of papers which did much to increase the precision with which temperatures could be determined. Of these papers it is only necessary to mention those on a comparator for thermometers, on radiation pyrometry, on the high temperature scale, on standards of light, on the platinum thermometer and the melting-point of platinum, and on the possibility of detecting the presence of icebergs by the temperature of the ocean, to show the nature and extent of his work. In recent years his interests have centred mainly in the applications of physics to problems of refrigeration and to the production of fire-resisting structures. In these fields his loss will be severely felt.

In the *Chemiker Zeitung* of April 15 the death is announced, at the age of sixty years, of Dr. F. Voigtländer, emeritus professor of chemistry at the University of Hamburg.

The U.S. Public Health Service has lost, by his death at the age of forty-eight, the skilled assistance of its assistant epidemiologist, Dr. David G. Willets. He had spent several years at Manila, at first in the biological laboratory of the Bureau of Science and afterward on the staff of the University of the Philippines. He had written many bulletins and monographs on pellagra, intestinal parasites, and other tropical problems.

Current Topics and Events.

The one hundred and fiftieth anniversary of the foundation of the Royal Academy of Belgium will be celebrated in Brussels on May 23-24. More than ninety delegates, representing forty-five academies in eighteen different countries, in addition to foreign associates of the Belgian Academy, are expected to attend the function. France is sending a number of representatives; the Institute of France alone will have thirty-six delegates. We learn from the Secretary of the Academy that the learned societies of Great Britain will be represented as follows: Royal Society, Sir William Leishman and Prof. H. Lamb (also representing the Cambridge Philosophical Society); Royal Society of Edinburgh, Sir George Berry; Royal Academy, Sir George Frampton, Sir Reginald Blomfield, and Mr. H. Hughes-Stanton; Royal Institute of British Architects, Sir John Burnet, Mr. J. Simpson, and Mr. P. Waterhouse; Royal Geographical Society, Sir Frederick Sykes; Royal Historical Society, Mr. G. M. T. Omond; British Academy, Sir Frederic Kenyon and Mr. H. Stuart-Jones; Chemical Society, Sir William Pope; Zoological Society, Dr. G. A. Boulenger and Dr. P. Chalmers Mitchell; Asiatic Society of Bengal, Sir Thomas H. Holland and Dr. Pascoe. The following British Associates of the Belgian Academy will be present: Sir Frank Dyson, Sir T. Erskine Holland, Sir Frederick Pollock, Sir Thomas Jackson, Sir John Lavery, and Mr. J. Pennell. The learned societies of Australia and New Zealand and the Royal Irish Academy have sent congratulatory addresses.
